Package ‘sna’

June 7, 2009

Version 2.0
Date 2009-06-07
Title Tools for Social Network Analysis
Author Carter T. Butts <buttsc@uci.edu>
Maintainer Carter T. Butts <buttsc@uci.edu>
Depends R (>= 2.0.0), utils
Suggests network, rgl, numDeriv, SparseM, statnet
Description A range of tools for social network analysis, including node and graph-level indices, structural distance and covariance methods, structural equivalence detection, p* modeling, random graph generation, and 2D/3D network visualization.
License GPL Version 2 or later

**add.isolates**

Add Isolates to a Graph

**Description**

Add `n` isolates to the graph (or graphs) in `dat`.

**Usage**

```r
call.add.isolates(dat, n, return.as.edgelist = FALSE)
```

**Arguments**

- `dat`: one or more input graphs.
- `n`: the number of isolates to add.
- `return.as.edgelist`: logical; should the input graph be returned as an edgelist (rather than an adjacency matrix)?
Details

If `dat` contains more than one graph, the `n` isolates are added to each member of `dat`.

Value

The updated graph(s).

Note

Isolate addition is particularly useful when computing structural distances between graphs of different orders; see the above reference for details.

Author(s)

Carter T. Butts ⟨buttsc@uci.edu⟩

`isolates`

Examples

```r
#Produce some random graphs

g <- rgraph(10, 5)
dim(g)

#Add 2 isolates to each graph in g

g <- add.isolates(g, 2)
dim(g)
g
```

Description

Takes posterior draws from Butts’ bayesian network accuracy/estimation model for multiple participant/observers (conditional on observed data and priors), using a Gibbs sampler.
Usage

bbnam(dat, model="actor", ...) 
bbnam.fixed(dat, nprior=0.5, em=0.25, ep=0.25, diag=FALSE, 
   mode="digraph", draws=1500, outmode="draws", anames=NULL, 
   onames=NULL) 
bbnam.pooled(dat, nprior=0.5, emprior=c(1,11), epprior=c(1,11), 
   diag=FALSE, mode="digraph", reps=5, draws=1500, burntime=500, 
   quiet=TRUE, anames=NULL, onames=NULL, compute.sqrtrhat=TRUE) 
bbnam.actor(dat, nprior=0.5, emprior=c(1,11), epprior=c(1,11), 
   diag=FALSE, mode="digraph", reps=5, draws=1500, burntime=500, 
   quiet=TRUE, anames=NULL, onames=NULL, compute.sqrtrhat=TRUE)

Arguments

dat 
   Input networks to be analyzed. This may be supplied in any reasonable form, 
   but must be reducible to an array of dimension \( m \times n \times n \), where \( n \) is \( |V(G)| \), the 
   first dimension indexes the observer (or information source), the second indexes 
   the sender of the relation, and the third dimension indexes the recipient of the 
   relation. (E.g., \( \text{dat}[i,j,k]=1 \) implies that \( i \) observed \( j \) sending the relation 
   in question to \( k \).) Note that only dichotomous data is supported at present, and 
   missing values are permitted; the data collection pattern, however, is assumed 
   to be ignorable, and hence the posterior draws are implicitly conditional on the 
   observation pattern.

model 
   String containing the error model to use; options are "actor", "pooled", 
   and "fixed".

... 
   Arguments to be passed by bbnam to the particular model method.

nprior 
   Network prior matrix. This must be a matrix of dimension \( n \times n \), containing 
   the arc/edge priors for the criterion network. (E.g., \( \text{nprior}[i,j] \) gives the 
   prior probability of \( i \) sending the relation to \( j \) in the criterion graph.) Non- 
   matrix values will be coerced/expanded to matrix form as appropriate. If no 
   network prior is provided, an uninformative prior on the space of networks will 
   be assumed (i.e., \( \Pr(i \rightarrow j) = 0.5 \)). Missing values are not allowed.

em 
   Probability of a false negative; this may be in the form of a single number, one 
   number per observation slice, one number per (directed) dyad, or one number 
   per dyadic observation (fixed model only).

ep 
   Probability of a false positive; this may be in the form of a single number, one 
   number per observation slice, one number per (directed) dyad, or one number 
   per dyadic observation (fixed model only).

emprior 
   Parameters for the (Beta) false negative prior; these should be in the form of an 
   \((\alpha,\beta)\) pair for the pooled model, and of an \( n \times 2 \) matrix of \((\alpha,\beta)\) pairs for the 
   actor model (or something which can be coerced to this form). If no emprior 
   is given, a weakly informative prior \((1,11)\) will be assumed; note that this may 
   be inappropriate, as described below. Missing values are not allowed.

epprior 
   Parameters for the (Beta) false positive prior; these should be in the form of an 
   \((\alpha,\beta)\) pair for the pooled model, and of an \( n \times 2 \) matrix of \((\alpha,\beta)\) pairs for the 
   actor model (or something which can be coerced to this form). If no epprior 
   is given, a weakly informative prior \((1,11)\) will be assumed; note that this may 
   be inappropriate, as described below. Missing values are not allowed.

diag 
   Boolean indicating whether loops (matrix diagonals) should be counted as data.

mode 
   A string indicating whether the data in question forms a "graph" or a "digraph"
**reps**  
Number of replicate chains for the Gibbs sampler (pooled and actor models only).

**draws**  
Integer indicating the total number of draws to take from the posterior distribution. Draws are taken evenly from each replication (thus, the number of draws from a given chain is draws/reps).

**burntime**  
Integer indicating the burn-in time for the Markov Chain. Each replication is iterated burntime times before taking draws (with these initial iterations being discarded); hence, one should realize that each increment to burntime increases execution time by a quantity proportional to reps. (pooled and actor models only)

**quiet**  
Boolean indicating whether MCMC diagnostics should be displayed (pooled and actor models only).

**outmode**  
posterior indicates that the exact posterior probability matrix for the criterion graph should be returned; otherwise draws from the joint posterior are returned instead (fixed model only).

**anames**  
A vector of names for the actors (vertices) in the graph.

**onames**  
A vector of names for the observers (possibly the actors themselves) whose reports are contained in the input data.

**compute.sqrtrhat**  
A boolean indicating whether or not Gelman et al.’s potential scale reduction measure (an MCMC convergence diagnostic) should be computed (pooled and actor models only).

**Details**

The bbnam models a set of network data as reflecting a series of (noisy) observations by a set of participants/observers regarding an uncertain criterion structure. Each observer is assumed to send false positives (i.e., reporting a tie when none exists in the criterion structure) with probability $e^+$, and false negatives (i.e., reporting that no tie exists when one does in fact exist in the criterion structure) with probability $e^-$. The criterion network itself is taken to be a Bernoulli (di)graph.

Note that the present model includes three variants:

1. **Fixed error probabilities**: Each edge is associated with a known pair of false negative/false positive error probabilities (provided by the researcher). In this case, the posterior for the criterion graph takes the form of a matrix of Bernoulli parameters, with each edge being independent conditional on the parameter matrix.

2. **Pooled error probabilities**: One pair of (uncertain) false negative/false positive error probabilities is assumed to hold for all observations. Here, we assume that the researcher’s prior information regarding these parameters can be expressed as a pair of Beta distributions, with the additional assumption of independence in the prior distribution. Note that error rates and edge probabilities are *not* independent in the joint posterior, but the posterior marginals take the form of Beta mixtures and Bernoulli parameters, respectively.

3. **Per observer (“actor”) error probabilities**: One pair of (uncertain) false negative/false positive error probabilities is assumed to hold for each observation slice. Again, we assume that prior knowledge can be expressed in terms of independent Beta distributions (along with the Bernoulli prior for the criterion graph) and the resulting posterior marginals are Beta mixtures and a Bernoulli graph. (Again, it should be noted that independence in the priors does *not* imply independence in the joint posterior!)

By default, the bbnam routine returns (approximately) independent draws from the joint posterior distribution, each draw yielding one realization of the criterion network and one collection of
accuracy parameters (i.e., probabilities of false positives/negatives). This is accomplished via a Gibbs sampler in the case of the pooled/actor model, and by direct sampling for the fixed probability model. In the special case of the fixed probability model, it is also possible to obtain directly the posterior for the criterion graph (expressed as a matrix of Bernoulli parameters); this can be controlled by the outmode parameter.

As noted, the taking of posterior draws in the nontrivial case is accomplished via a Markov Chain Monte Carlo method, in particular the Gibbs sampler; the high dimensionality of the problem ($O(n^2 + 2n)$) tends to preclude more direct approaches. At present, chain burn-in is determined ex ante on a more or less arbitrary basis by specification of the burntime parameter. Eventually, a more systematic approach will be utilized. Note that insufficient burn-in will result in inaccurate posterior sampling, so it’s not wise to skimp on burn time where otherwise possible. Similarly, it is wise to employ more than one Markov Chain (set by reps), since it is possible for trajectories to become “trapped” in metastable regions of the state space. Number of draws per chain being equal, more replications are usually better than few; consult Gelman et al. for details. A useful measure of chain convergence, Gelman and Rubin’s potential scale reduction ($\sqrt{R}$), can be computed using the compute.sqrtrhat parameter. The potential scale reduction measure is an ANOVA-like comparison of within-chain versus between-chain variance; it approaches 1 (from above) as the chain converges, and longer burn-in times are strongly recommended for chains with scale reductions in excess of 1.2 or thereabouts.

Finally, a cautionary concerning prior distributions: it is important that the specified priors actually reflect the prior knowledge of the researcher; otherwise, the posterior will be inadequately informed. In particular, note that an uninformative prior on the accuracy probabilities implies that it is a priori equally probable that any given actor’s observations will be informative or negatively informative (i.e., that $i$ observing $j$ sending a tie to $k$ reduces $Pr(j \rightarrow k)$). This is a highly unrealistic assumption, and it will tend to produce posteriors which are bimodal (one mode being related to the “informative” solution, the other to the “negatively informative” solution). Currently, the default error parameter prior is Beta(1,11), which is both diffuse and which renders negatively informative observers extremely improbable (i.e., on the order of 1e-6). Another plausible but still fairly diffuse prior would be Beta(3,5), which reduces the prior probability of an actor’s being negatively informative to 0.16, and the prior probability of any given actor’s being more than 50% likely to make a particular error (on average) to around 0.22. (This prior also puts substantial mass near the 0.5 point, which would seem consonant with the BKS studies.) For network priors, a reasonable starting point can often be derived by considering the expected mean degree of the criterion graph: if $d$ represents the user’s prior expectation for the mean degree, then $d/(N-1)$ is a natural starting point for the cell values of nprior. Butts (2003) discusses a number of issues related to choice of priors for the bbnam model, and users should consult this reference if matters are unclear before defaulting to the uninformative solution.

Value

An object of class bbnam, containing the posterior draws. The components of the output are as follows:

- anames: A vector of actor names.
- draws: An integer containing the number of draws.
- em: A matrix containing the posterior draws for probability of producing false negatives, by actor.
- ep: A matrix containing the posterior draws for probability of producing false positives, by actor.
- nactors: An integer containing the number of actors.
- net: An array containing the posterior draws for the criterion network.
An integer indicating the number of replicate chains used by the Gibbs sampler.

Note

As indicated, the posterior draws are conditional on the observed data, and hence on the data collection mechanism if the collection design is non-ignorable. Complete data (e.g., a CSS) and random tie samples are examples of ignorable designs; see Gelman et al. for more information concerning ignorability.

Estimate Bayes Factors for the bbnam

Description

This function uses monte carlo integration to estimate the BFs, and tests the fixed probability, pooled, and pooled by actor models. (See bbnam for details.)

Usage

```r
bbnam.bf(dat, nprior=0.5, em.fp=0.5, ep.fp=0.5, emprior.pooled=c(1, 11),
epprior.pooled=c(1, 11), emprior.actor=c(1, 11), epprior.actor=c(1, 11),
diag=FALSE, mode="digraph", reps=1000)
```

Arguments

dat Input networks to be analyzed. This may be supplied in any reasonable form, but must be reducible to an array of dimension \(m \times n \times n\), where \(n = |V(G)|\), the first dimension indexes the observer (or information source), the second indexes the sender of the relation, and the third dimension indexes the recipient of the relation. (E.g., \(\text{dat}[i, j, k] = 1\) implies that \(i\) observed \(j\) sending the relation in question to \(k\).) Note that only dichotomous data is supported at present, and missing values are permitted; the data collection pattern, however, is assumed to be ignorable, and hence the posterior draws are implicitly conditional on the observation pattern.

nprior Network prior matrix. This must be a matrix of dimension \(n \times n\), containing the arc/edge priors for the criterion network. (E.g., \(\text{nprior}[i, j]\) gives the prior probability of \(i\) sending the relation to \(j\) in the criterion graph.) Non-matrix values will be coerced/expanded to matrix form as appropriate. If no network prior is provided, an uninformative prior on the space of networks will be assumed (i.e., \(\Pr(i \rightarrow j) = 0.5\)). Missing values are not allowed.

em.fp Probability of false negatives for the fixed probability model

ep.fp Probability of false positives for the fixed probability model

emprior.pooled \((\alpha, \beta)\) pairs for the (beta) false negative prior under the pooled model

epprior.pooled \((\alpha, \beta)\) pairs for the (beta) false positive prior under the pooled model

emprior.actor Matrix of per observer \((\alpha, \beta)\) pairs for the (beta) false negative prior under the per observer/actor model, or something that can be coerced to this form

epprior.actor Matrix of per observer \((\alpha, \beta)\) pairs for the (beta) false positive prior under the per observer/actor model, or something that can be coerced to this form

diag Boolean indicating whether or not the diagonal should be treated as valid data. Set this true if and only if the criterion graph can contain loops. Diag is false by default.

mode String indicating the type of graph being evaluated. "digraph" indicates that edges should be interpreted as directed; "graph" indicates that edges are undirected. Mode is set to "digraph" by default.

reps Number of Monte Carlo draws to take
Details

The bbnam model (detailed in the bbnam function help) is a fairly simple model for integrating informant reports regarding social network data. bbnam bf computes log Bayes Factors (integrated likelihood ratios) for the three error submodels of the bbnam: fixed error probabilities, pooled error probabilities, and per observer/actor error probabilities.

By default, bbnam bf uses weakly informative Beta(1,11) priors for false positive and false negative rates, which may not be appropriate for all cases. (Likewise, the initial network prior is uninformative.) Users are advised to consider adjusting the error rate priors when using this function in a practical context; for instance, it is often reasonable to expect higher false negative rates (on average) than false positive rates, and to expect the criterion graph density to be substantially less than 0.5. See the reference below for a discussion of this issue.

Value

An object of class bayes.factor.

Note

It is important to be aware that the model parameter priors are essential components of the models to be compared; inappropriate parameter priors will result in misleading Bayes Factors.

Compute the Betweenness Centrality Scores of Network Positions

**Description**

`betweenness` takes one or more graphs (`dat`) and returns the betweenness centralities of positions (selected by `nodes`) within the graphs indicated by `g`. Depending on the specified mode, betweenness on directed or undirected geodesics will be returned; this function is compatible with `centralization`, and will return the theoretical maximum absolute deviation (from maximum) conditional on size (which is used by `centralization` to normalize the observed centralization score).

**Usage**

```r
betweenness(dat, g=1, nodes=NULL, gmode="digraph", diag=FALSE, tmaxdev=FALSE, cmode="directed", geodist.precomp=NULL, rescale=FALSE, ignore.eval=TRUE)
```

**Arguments**

- `dat`: one or more input graphs.
- `g`: integer indicating the index of the graph for which centralities are to be calculated (or a vector thereof). By default, `g`=1.
- `nodes`: vector indicating which nodes are to be included in the calculation. By default, all nodes are included.
- `gmode`: string indicating the type of graph being evaluated. "digraph" indicates that edges should be interpreted as directed; "graph" indicates that edges are undirected. `gmode` is set to "digraph" by default.
- `diag`: boolean indicating whether or not the diagonal should be treated as valid data. Set this true if and only if the data can contain loops. `diag` is `FALSE` by default.
- `tmaxdev`: boolean indicating whether or not the theoretical maximum absolute deviation from the maximum nodal centrality should be returned. By default, `tmaxdev`=`FALSE`.
- `cmode`: string indicating the type of betweenness centrality being computed (directed or undirected geodesics, or a variant form – see below).
- `geodist.precomp`: A `geodist` object precomputed for the graph to be analyzed (optional)
- `rescale`: if true, centrality scores are rescaled such that they sum to 1.
- `ignore.eval`: logical; ignore edge values when computing shortest paths?

**Details**

The shortest-path betweenness of a vertex, `v`, is given by

\[ C_B(v) = \sum_{i,j\neq k,v,j\neq v} \frac{g_{vij}}{g_{ij}} \]

where \(g_{ijk}\) is the number of geodesics from `i` to `k` through `j`. Conceptually, high-betweenness vertices lie on a large number of non-redundant shortest paths between other vertices; they can thus be thought of as "bridges" or "boundary spanners."
Several variant forms of shortest-path betweenness exist, and can be selected using the \texttt{cmode} argument. Supported options are as follows:

\textbf{directed} Standard betweenness (see above), calculated on directed pairs. (This is the default option.)

\textbf{undirected} Standard betweenness (as above), calculated on undirected pairs (undirected graphs only).

\textbf{endpoints} Standard betweenness, with direct connections counted towards ego's score. This expresses the intuition that individuals' control over their own direct contacts should be considered in their total score (e.g., when betweenness is interpreted as a measure of information control).

\textbf{proximalsrc} Borgatti's proximal source betweenness, given by

$$C_B(v) = \sum_{i,j: i \neq v, i \neq j \rightarrow v} \frac{g_{uvj}}{g_{ij}}.$$ 

This variant allows betweenness to accumulate only for the last intermediating vertex in each incoming geodesic; this expresses the notion that, by serving as the "proximal source" for the target, this particular intermediary will in some settings have greater influence or control than other intervening parties.

\textbf{proximaltar} Borgatti's proximal target betweenness, given by

$$C_B(v) = \sum_{i,j: i \neq v, i \rightarrow v, j \neq v} \frac{g_{uvj}}{g_{ij}}.$$ 

This counterpart to proximal source betweenness (above) allows betweenness to accumulate only for the first intermediating vertex in each outgoing geodesic; this expresses the notion that, by serving as the "proximal target" for the source, this particular intermediary will in some settings have greater influence or control than other intervening parties.

\textbf{proximalsum} The sum of Borgatti’s proximal source and proximal target betweenness scores (above); this may be used when either role is regarded as relevant to the betweenness calculation.

\textbf{lengthscaled} Borgatti and Everett's length-scaled betweenness, given by

$$C_B(v) = \sum_{i,j: i \neq j, i \neq v, j \neq v} \frac{1}{d_{ij}} \frac{g_{uvj}}{g_{ij}},$$

where \(d_{ij}\) is the geodesic distance from \(i\) to \(j\). This measure adjusts the standard betweenness score by downweighting long paths (e.g., as appropriate in circumstances for which such paths are less-often used).

\textbf{linearscaled} Geisberger et al.'s linearly-scaled betweenness:

$$C_B(v) = \sum_{i,j: i \neq j, i \neq v, j \neq v} \frac{1}{d_{ij}} \frac{g_{uvj}}{g_{ij}}.$$ 

This variant modifies the standard betweenness score by giving more weight to intermediaries which are closer to their targets (much like proximal source betweenness, above). This may be of use when those near the end of a path have greater direct control over the flow of influence or resources than those near its source.

See Brandes (2008) for details and additional references. Geodesics for all of the above can be calculated using valued edges by setting \texttt{ignore.eval=TRUE}. Edge values are interpreted as distances for this purpose; proximity data should be transformed accordingly before invoking this routine.
Value

A vector, matrix, or list containing the betweenness scores (depending on the number and size of
the input graphs).

Warning

Rescale may cause unexpected results if all actors have zero betweenness.

Note

Judicious use of geodist.precomp can save a great deal of time when computing multiple
path-based indices on the same network.

bicomponent.dist Calculate the Bicomponents of a Graph

Description

bicomponent.dist returns the bicomponents of an input graph, along with size distribution
and membership information.

Usage

bicomponent.dist(dat, symmetrize = c("strong", "weak"))
**Arguments**

- **dat**: a graph or graph stack.
- **symmetrize**: symmetrization rule to apply when pre-processing the input (see `symmetrize`).

**Details**

The bicomponents of undirected graph \( G \) are its maximal 2-connected vertex sets. `bicomponent.dist` calculates the bicomponents of \( G \), after first coercing to undirected form using the symmetrization rule in `symmetrize`. In addition to bicomponent memberships, various summary statistics regarding the bicomponent distribution are returned; see below.

**Value**

A list containing

- **members**: A list, with one entry per bicomponent, containing component members.
- **memberships**: A vector of component memberships, by vertex. (Note: memberships may not be unique.) Vertices not belonging to any bicomponent have membership values of `NA`.
- **csize**: A vector of component sizes, by bicomponent.
- **cdist**: A vector of length \(|V(G)|\) with the (unnormalized) empirical distribution function of bicomponent sizes.

**Note**

Remember that bicomponents can intersect; when this occurs, the relevant vertices’ entries in the membership vector are assigned to one of the overlapping bicomponents on an arbitrary basis. The `members` element of the return list is the safe way to recover membership information.

**Author(s)**

Carter T. Butts (butts@uci.edu)

**References**

**See Also**

`component.dist`, `cutpoints`

**Examples**

```r
# Draw a moderately sparse graph
g <- rgraph(25, tp=2/24, mode="graph")

# Compute the bicomponents
bicomponent.dist(g)
```
**blockmodel**

*Generate Blockmodels Based on Partitions of Network Positions*

**Description**

Given a set of equivalence classes (in the form of an `equiv.clust` object, `hclust` object, or membership vector) and one or more graphs, `blockmodel` will form a blockmodel of the input graph(s) based on the classes in question, using the specified block content type.

**Usage**

```r
blockmodel(dat, ec, k=NULL, h=NULL, block.content="density", plabels=NULL, glabels=NULL, rlabels=NULL, mode="digraph", diag=FALSE)
```

**Arguments**

- `dat` one or more input graphs.
- `ec` equivalence classes, in the form of an object of class `equiv.clust` or `hclust`, or a membership vector.
- `k` the number of classes to form (using `cutree`).
- `h` the height at which to split classes (using `cutree`).
- `block.content` string indicating block content type (see below).
- `plabels` a vector of labels to be applied to the individual nodes.
- `glabels` a vector of labels to be applied to the graphs being modeled.
- `rlabels` a vector of labels to be applied to the (reduced) roles.
- `mode` a string indicating whether we are dealing with graphs or digraphs.
- `diag` a boolean indicating whether loops are permitted.

**Details**

Unless a vector of classes is specified, `blockmodel` forms its eponymous models by using `cutree` to cut an equivalence clustering in the fashion specified by `k` and `h`. After forming clusters (roles), the input graphs are reordered and blockmodel reduction is applied. Currently supported reductions are:

1. `density`: block density, computed as the mean value of the block
2. `meanrowsum`: mean row sums for the block
3. `meancolsum`: mean column sums for the block
4. `sum`: total block sum
5. `median`: median block value
6. `min`: minimum block value
7. `max`: maximum block value
8. **types**: semi-intelligent coding of blocks by “type.” Currently recognized types are (in order of precedence) “NA” (i.e., blocks with no valid data), “null” (i.e., all values equal to zero), “complete” (i.e., all values equal to 1), “1 covered” (i.e., all rows/cols contain a 1), “1 row-covered” (i.e., all rows contain a 1), “1 col-covered” (i.e., all cols contain a 1), and “other” (i.e., none of the above).

Density or median-based reductions are probably the most interpretable for most conventional analyses, though type-based reduction can be useful in examining certain equivalence class hypotheses (e.g., 1 covered and null blocks can be used to infer regular equivalence classes). Once a given reduction is performed, the model can be analyzed and/or expansion can be used to generate new graphs based on the inferred role structure.

**Value**

An object of class `blockmodel`.

**Author(s)**

Carter T. Butts (butsc@uci.edu)

**References**

**See Also**

`equiv.clust`, `blockmodel.expand`

**Examples**

```r
#Create a random graph with _some_ edge structure
g.p<-sapply(runif(20,0,1),rep,20)  #Create a matrix of edge probabilities
g<-rgraph(20,tprob=g.p)  #Draw from a Bernoulli graph distribution

eq<-equiv.clust(g)  #Cluster based on structural equivalence
b<-blockmodel(g,eq,h=10)  #Form a blockmodel with distance relaxation of 10
plot(b)  #Plot it
```
**blockmodel.expand**  
*Generate a Graph (or Stack) from a Given Blockmodel Using Particular Expansion Rules*

**Description**

`blockmodel.expand` takes a blockmodel and an expansion vector, and expands the former by making copies of the vertices.

**Usage**

`blockmodel.expand(b, ev, mode="digraph", diag=FALSE)`

**Arguments**

- `b`: blockmodel object.
- `ev`: a vector indicating the number of copies to make of each class (respectively).
- `mode`: a string indicating whether the result should be a “graph” or “digraph”.
- `diag`: a boolean indicating whether or not loops should be permitted.

**Details**

The primary use of blockmodel expansion is in generating test data from a blockmodeling hypothesis. Expansion is performed depending on the content type of the blockmodel; at present, only density is supported. For the density content type, expansion is performed by interpreting the interclass density as an edge probability, and by drawing random graphs from the Bernoulli parameter matrix formed by expanding the density model. Thus, repeated calls to `blockmodel.expand` can be used to generate a sample for monte carlo null hypothesis tests under a Bernoulli graph model.

**Value**

An adjacency matrix, or stack thereof.

**Note**

Eventually, other content types will be supported.

Fit a Biased Net Model

Description

Fits a biased net model to an input graph, using moment-based or maximum pseudolikelihood techniques.

Usage

bn(dat, method = c("mple.triad", "mple.dyad", "mple.edge", "mtle"), param.seed = NULL, param.fixed = NULL, optim.method = "BFGS", optim.control = list(), epsilon = 1e-05)

Arguments

dat a single input graph.

method the fit method to use (see below).

param.seed seed values for the parameter estimates.

param.fixed parameter values to fix, if any.

optim.method method to be used by optim.

optim.control control parameter for optim.

epsilon tolerance for convergence to extreme parameter values (i.e., 0 or 1).
The biased net model stems from early work by Rapoport, who attempted to model networks via a hypothetical "tracing" process. This process may be described loosely as follows. One begins with a small "seed" set of vertices, each member of which is assumed to nominate (generate ties to) other members of the population with some fixed probability. These members, in turn, may nominate new members of the population, as well as members who have already been reached. Such nominations may be "biased" in one fashion or another, leading to a non-uniform growth process. Specifically, let $e_{ij}$ be the random event that vertex $i$ nominates vertex $j$ when reached. Then the conditional probability of $e_{ij}$ is given by

$$\Pr(e_{ij}|T) = 1 - (1 - \Pr(B_e)) \prod_k (1 - \Pr(B_k|T))$$

where $T$ is the current state of the trace, $B_e$ is the a Bernoulli event corresponding to the baseline probability of $e_{ij}$, and the $B_k$ are "bias events." Bias events are taken to be independent Bernoulli trials, given $T$, such that $e_{ij}$ is observed with certainty if any bias event occurs. The specification of a biased net model, then, involves defining the various bias events (which, in turn, influence the structure of the network).

Although other events have been proposed, the primary bias events employed in current biased net models are the "parent bias" (a tendency to return nominations); the "sibling bias" (a tendency to nominate alters who were nominated by the same third party); and the "double role bias" (a tendency to nominate alters who are both siblings and parents). These bias events, together with the baseline edge events, are used to form the standard biased net model. It is standard to assume homogeneity within bias class, leading to the four parameters $\pi$ (probability of a parent bias event), $\sigma$ (probability of a sibling bias event), $\rho$ (probability of a double role bias event), and $d$ (probability of a baseline event).

Unfortunately, there is no simple expression for the likelihood of a graph given these parameters (and hence, no basis for likelihood based inference). However, Skvoretz et al. have derived a class of maximum pseudo-likelihood estimators for the the biased net model, based on local approximations to the likelihood at the edge, dyad, or triad level. These estimators may be employed within $bn$ by selecting the appropriate MPLE for the method argument. Alternately, it is also possible to derive expected triad census rates for the biased net model, allowing an estimator which maximizes the likelihood of the observed triad census (essentially, a method of moments procedure). This last may be selected via the argument mode="mtle". In addition to estimating model parameters, $bn$ generates predicted edge, dyad, and triad census statistics, as well as structure statistics (using the Fararo-Sunshine recurrence). These can be used to evaluate goodness-of-fit.

print, summary, and plot methods are available for $bn$ objects. See rgbn for simulation from biased net models.

Value

An object of class $bn$.

Note

Asymptotic properties of the MPLE are not known for this model. Caution is strongly advised.

bonpow

Find Bonacich Power Centrality Scores of Network Positions

Description

bonpow takes one or more graphs (dat) and returns the Boncich power centralities of positions (selected by nodes) within the graphs indicated by g. The decay rate for power contributions is specified by exponent (1 by default). This function is compatible with centralization, and will return the theoretical maximum absolute deviation (from maximum) conditional on size (which is used by centralization to normalize the observed centralization score).

Usage

bonpow(dat, g=1, nodes=NULL, gmode="digraph", diag=FALSE, tmaxdev=FALSE, exponent=1, rescale=FALSE, tol=1e-07)

Arguments

dat one or more input graphs.

g integer indicating the index of the graph for which centralities are to be calculated (or a vector thereof). By default, g=1.
nodes vector indicating which nodes are to be included in the calculation. By default, all nodes are included.

gmode string indicating the type of graph being evaluated. "digraph" indicates that edges should be interpreted as directed; "graph" indicates that edges are undirected. This is currently ignored.

diag boolean indicating whether or not the diagonal should be treated as valid data. Set this true if and only if the data can contain loops. Diag is FALSE by default.

tmaxdev boolean indicating whether or not the theoretical maximum absolute deviation from the maximum nodal centrality should be returned. By default, tmaxdev=FALSE.

Details

Bonacich’s power centrality measure is defined by $C_{BP}(\alpha, \beta) = \alpha (1 - \beta A)^{-1} A 1$, where $\beta$ is an attenuation parameter (set here by exponent) and $A$ is the graph adjacency matrix. (The coefficient $\alpha$ acts as a scaling parameter, and is set here (following Bonacich (1987)) such that the sum of squared scores is equal to the number of vertices. This allows 1 to be used as a reference value for the “middle” of the centrality range.) When $\beta \to 1/\lambda_A$ (the reciprocal of the largest eigenvalue of $A$), this is to within a constant multiple of the familiar eigenvector centrality score; for other values of $\beta$, the behavior of the measure is quite different. In particular, $\beta$ gives positive and negative weight to even and odd walks, respectively, as can be seen from the series expansion $C_{BP}(\alpha, \beta) = \alpha \sum_{k=0}^{\infty} \beta^k A^{k+1} 1$ which converges so long as $|\beta| < 1/\lambda_A$. The magnitude of $\beta$ controls the influence of distant actors on ego’s centrality score, with larger magnitudes indicating slower rates of decay. (High rates, hence, imply a greater sensitivity to edge effects.)

Interpretively, the Bonacich power measure corresponds to the notion that the power of a vertex is recursively defined by the sum of the power of its alters. The nature of the recursion involved is then controlled by the power exponent: positive values imply that vertices become more powerful as their alters become more powerful (as occurs in cooperative relations), while negative values imply that vertices become more powerful only as their alters become weaker (as occurs in competitive or antagonistic relations). The magnitude of the exponent indicates the tendency of the effect to decay across long walks; higher magnitudes imply slower decay. One interesting feature of this measure is its relative instability to changes in exponent magnitude (particularly in the negative case). If your theory motivates use of this measure, you should be very careful to choose a decay parameter on a non-ad hoc basis.

Value

A vector, matrix, or list containing the centrality scores (depending on the number and size of the input graphs).

Warning

Singular adjacency matrices cause no end of headaches for this algorithm; thus, the routine may fail in certain cases. This will be fixed when I get a better algorithm. bonpow will not symmetrize your data before extracting eigenvectors; don’t send this routine asymmetric matrices unless you really mean to do so.
Note

The theoretical maximum deviation used here is not obtained with the star network, in general. For positive exponents, at least, the symmetric maximum occurs for an empty graph with one complete dyad (the asymmetric maximum is generated by the outstar). UCINET V seems not to adjust for this fact, which can cause some oddities in their centralization scores (thus, don’t expect to get the same numbers with both packages).

```

---

**brokerage**

*Perform a Gould-Fernandez Brokerage Analysis*

**Description**

Performs the brokerage analysis of Gould and Fernandez on one or more input graphs, given a class membership vector.

**Usage**

`brokerage(g, cl)`

**Arguments**

- `g` one or more input graphs.
- `cl` a vector of class memberships.
Details

Gould and Fernandez (following Marsden and others) describe brokerage as the role played by a social actor who mediates contact between two alters. More formally, vertex \( v \) is a broker for distinct vertices \( a \) and \( b \) iff \( a \rightarrow v \rightarrow b \) and \( a \not\rightarrow b \). Where actors belong to a priori distinct groups, group membership may be used to segment brokerage roles into particular types. Let \( A \rightarrow B \rightarrow C \) denote the two-path associated with a brokerage structure, such that some vertex from group \( B \) brokers the connection from some vertex from group \( A \) to a vertex in group \( C \). The types of brokerage roles defined by Gould and Fernandez (and their accompanying two-path structures) are then defined in terms of group membership as follows:

- **\( w_I \)** Coordinator role; the broker mediates contact between two individuals from his or her own group. Two-path structure: \( A \rightarrow A \rightarrow A \)
- **\( w_O \)** Itinerant broker role; the broker mediates contact between two individuals from a single group to which he or she does not belong. Two-path structure: \( A \rightarrow B \rightarrow A \)
- **\( b_{IO} \)** Gatekeeper role; the broker mediates an incoming contact from an out-group member to an in-group member. Two-path structure: \( A \rightarrow B \rightarrow A \)
- **\( b_{OI} \)** Representative role; the broker mediates an outgoing contact from an in-group member to an out-group member. Two-path structure: \( A \rightarrow A \rightarrow B \)
- **\( b_O \)** Liaison role; the broker mediates contact between two individuals from different groups, neither of which is the group to which he or she belongs. Two-path structure: \( A \rightarrow B \rightarrow C \)
- **\( t \)** Total (cumulative) brokerage role occupancy. (Any of the above two-paths.)

The brokerage score for a given vertex with respect to a given role is the number of ordered pairs having the appropriate group membership(s) brokered by said vertex. Brokerage computes the brokerage scores for each vertex, given an input graph and vector of class memberships. Aggregate scores are also computed at the graph level, which correspond to the total frequency of each role type within the network structure. Expectations and variances of the brokerage scores conditional on size and density are computed, along with approximate \( z \)-tests for incidence of brokerage. (Note that the accuracy of the normality assumption is not known in the general case; see Gould and Fernandez (1989) for details. Simulation-based tests may be desirable as an alternative.)

Value

An object of class `brokerage`, containing the following elements:

- **raw.nli** The matrix of observed brokerage scores, by vertex
- **exp.nli** The matrix of expected brokerage scores, by vertex
- **sd.nli** The matrix of predicted brokerage score standard deviations, by vertex
- **z.nli** The matrix of standardized brokerage scores, by vertex
- **raw.gli** The vector of observed aggregate brokerage scores
- **exp.gli** The vector of expected aggregate brokerage scores
- **sd.gli** The vector of predicted aggregate brokerage score standard deviations
- **z.gli** The vector of standardized aggregate brokerage scores
- **exp.grp** The matrix of expected brokerage scores, by group
- **sd.grp** The matrix of predicted brokerage score standard deviations, by group
- **cl** The vector of class memberships
- **clid** The original class names
- **n** The input class sizes
- **N** The order of the input network

centralgraph  Find the Central Graph of a Labeled Graph Stack

Description

Returns the central graph of a set of labeled graphs, i.e. that graph in which i->j iff i->j in >=50% of the graphs within the set. If normalize==TRUE, then the value of the i,jth edge is given as the proportion of graphs in which i->j.

Usage

centralgraph(dat, normalize=FALSE)

Arguments

dat  one or more input graphs.
normalize  boolean indicating whether the results should be normalized. The result of this is the "mean matrix". By default, normalize==FALSE.

Details

The central graph of a set of graphs S is that graph C which minimizes the sum of Hamming distances between C and G in S. As such, it turns out (for the dichotomous case, at least), to be analogous to both the mean and median for sets of graphs. The central graph is useful in a variety of contexts; see the references below for more details.

Value

A matrix containing the central graph (or mean matrix)
Note

0.5 is used as the cutoff value regardless of whether or not the data is dichotomous (as is tacitly assumed). The routine is unaffected by data type when normalize==TRUE.

#Now, look at the mean matrix
cg<-centralgraph(dat,normalize=TRUE)
print(cg)

centralization

Find the Centralization of a Given Network, for Some Measure of Centrality

Description

Centralization returns the centralization GLI (graph-level index) for a given graph in dat, given a (node) centrality measure FUN. Centralization follows Freeman’s (1979) generalized definition of network centralization, and can be used with any properly defined centrality measure. This measure must be implemented separately; see the references below for examples.

Usage

centralization(dat, FUN, g=NULL, mode="digraph", diag=FALSE, normalize=TRUE, ...)

Arguments

dat
    one or more input graphs.
FUN
    Function to return nodal centrality scores.
g
    Integer indicating the index of the graph for which centralization should be computed. By default, all graphs are employed.
centralization

mode String indicating the type of graph being evaluated. "digraph" indicates that edges should be interpreted as directed; "graph" indicates that edges are undirected. mode is set to "digraph" by default.

diag Boolean indicating whether or not the diagonal should be treated as valid data. Set this true if and only if the data can contain loops. diag is FALSE by default.

normalize Boolean indicating whether or not the centralization score should be normalized to the theoretical maximum. (Note that this function relies on FUN to return this value when called with tmaxdev==TRUE.) By default, tmaxdev==TRUE.

... Additional arguments to FUN.

Details

The centralization of a graph G for centrality measure $C(v)$ is defined (as per Freeman (1979)) to be:

$$C^*(G) = \sum_{i\in V(G)} \max_{v\in V(G)} (C(v)) - C(i)$$

Or, equivalently, the absolute deviation from the maximum of $C$ on G. Generally, this value is normalized by the theoretical maximum centralization score, conditional on $|V(G)|$. (Here, this functionality is activated by normalize.) Centralization depends on the function specified by FUN to return the vector of nodal centralities when called with dat and g, and to return the theoretical maximum value when called with the above and tmaxdev==TRUE. For an example of such a centrality routine, see degree.

Value

The centralization of the specified graph.

Note

See cugtest for null hypothesis tests involving centralization scores.

# How about on total (Freeman) degree?
centralization(dat,g=3,degree)

clique.census

Compute Cycle Census Information

Description

clique.census computes clique census statistics on one or more input graphs. In addition to aggregate counts of maximal cliques, results may be disaggregated by vertex and co-membership information may be computed.

Usage

clique.census(dat, mode = "digraph", tabulate.by.vertex = TRUE,
clique.comembership = c("none", "sum", "bysize"), enumerate = TRUE)

Arguments

dat one or more input graphs.
mode "digraph" for directed graphs, or "graph" for undirected graphs.
tabulate.by.vertex logical; should maximal clique counts be tabulated by vertex?
clique.comembership the type of clique co-membership information to be tabulated, if any. "sum" returns a vertex by vertex matrix of clique co-membership counts; these are disaggregated by clique size if "bysize" is used. If "none" is given, no co-membership information is computed.
enumerate logical; should an enumeration of all maximal cliques be returned?

Details

A (maximal) clique is a maximal set of mutually adjacent vertices. Cliques are important for their role as cohesive subgroups, but show up in many other contexts as well.

A subgraph census statistic is a function which, for any given graph and subgraph, gives the number of copies of the latter contained in the former. A collection of subgraph census statistics is referred to as a subgraph census; widely used examples include the dyad and triad censuses, implemented in sna by the dyad.census and triad.census functions (respectively). Likewise, kpath.census and kcyle.census compute a range of census statistics related to $k$-paths and $k$-cycles. clique.census provides similar functionality for the census of maximal cliques, including:

- Aggregate counts of maximal cliques by size.
- Counts of cliques to which each vertex belongs (when tabulate.byvertex==TRUE).
• Counts of clique co-memberships, potentially disaggregated by size (when the appropriate co-membership argument is set to `bylength`).

These calculations are intrinsically expensive (clique enumeration is NP hard in the general case), and users should be aware that computing the census can be impractical on large graphs (unless they are very sparse). On the other hand, the algorithm employed here (a variant of Makino and Uno (2004)) is generally fast enough to support enumeration for even dense graphs of several hundred vertices on a typical desktop computer.

Calling this function with `mode=="digraph"`, forces an initial symmetrization step, which can be avoided with `mode=="graph"`. While incorrectly employing the default is harmless (except for the relatively small cost of verifying symmetry), setting `mode=="graph"` incorrectly may result in problematic behavior. When in doubt, stick with the default.

Value

A list with the following elements:

- **clique.count**
  
  If `tabulate.byvertex==FALSE`, a vector of aggregate counts by clique size. Otherwise, a matrix whose first column is a vector of aggregate clique counts, and whose succeeding columns contain vectors of clique counts for each vertex.

- **clique.comemb**
  
  If `clique.comembership!="none"`, a matrix or array containing co-membership in cliques by vertex pairs. If `clique.comembership=="sum"`, only a matrix of co-memberships is returned; if `bysize` is used, however, co-memberships are returned in a `maxsize` by `n` by `n` array whose `i,j,k`th cell is the number of cliques of size `i` containing `j` and `k` (with `maxsize` being the size of the largest maximal clique).

- **cliques**
  
  If `enumerate=TRUE`, a list of length equal to the maximum clique size, each element of which is in turn a list of all cliques of corresponding size (given as vectors of vertices).

Warning

The computational cost of calculating cliques grows very sharply in size and network density. It is possible that the expected completion time for your calculation may exceed your life expectancy (and those of subsequent generations).

Closeness

Closeness computes the Closeness Centrality Scores of Network Positions.

Description

closeness takes one or more graphs (dat) and returns the closeness centralities of positions (selected by nodes) within the graphs indicated by g. Depending on the specified mode, closeness on directed or undirected geodesics will be returned; this function is compatible with centralization, and will return the theoretical maximum absolute deviation (from maximum) conditional on size (which is used by centralization to normalize the observed centralization score).

Usage

closeness(dat, g=1, nodes=NULL, gmode="digraph", diag=FALSE,
tmaxdev=FALSE, cmode="directed", geodist.precomp=NULL,
rescale=FALSE, ignore.eval=TRUE)

Arguments

dat one or more input graphs.
g integer indicating the index of the graph for which centralities are to be calculated (or a vector thereof). By default, g=1.
nodes list indicating which nodes are to be included in the calculation. By default, all nodes are included.
gmode string indicating the type of graph being evaluated. "digraph" indicates that edges should be interpreted as directed; "graph" indicates that edges are undirected. gmode is set to "digraph" by default.
diag boolean indicating whether or not the diagonal should be treated as valid data. Set this true if and only if the data can contain loops. diag is FALSE by default.
tmaxdev boolean indicating whether or not the theoretical maximum absolute deviation from the maximum nodal centrality should be returned. By default, tmaxdev==FALSE.
cmode string indicating the type of closeness centrality being computed (distances on directed or undirected pairs, or an alternate measure).
geodist.precomp a geodist object precomputed for the graph to be analyzed (optional)
rescale if true, centrality scores are rescaled such that they sum to 1.
ignore.eval logical; should edge values be ignored when calculating geodesics?
The closeness of a vertex $v$ is defined as

$$C_C(v) = \frac{|V(G)| - 1}{\sum_{i:i \neq v} d(v,i)}$$

where $d(i,j)$ is the geodesic distance between $i$ and $j$ (where defined). Closeness is ill-defined on disconnected graphs; in such cases, this routine substitutes $\text{Inf}$. It should be understood that this modification is not canonical (though it is common), but can be avoided by not attempting to measure closeness on disconnected graphs in the first place! Intuitively, closeness provides an index of the extent to which a given vertex has short paths to all other vertices in the graph; this is one reasonable measure of the extent to which a vertex is in the “middle” of a given structure.

An alternate form of closeness (whose origin is obscure) is obtained by taking the sum of the inverse distances to each vertex, i.e.

$$C_C(v) = \sum_{i:i \neq v} \frac{1}{d(v,i)}$$

This measure correlates well with the standard form of closeness where both are well-defined, but lacks the latter’s pathological behavior on disconnected graphs. Computation of alternate closeness may be performed via the argument `cmode="suminvdir"` (directed case) and `cmode="suminvundir"` (undirected case). The corresponding arguments `cmode="directed"` and `cmode="undirected"` return the standard closeness scores in the directed or undirected cases (respectively).

Value

A vector, matrix, or list containing the closeness scores (depending on the number and size of the input graphs).

Note

Judicious use of `geodist.precomp` can save a great deal of time when computing multiple path-based indices on the same network.

centralization

Examples

g<-rgraph(10)       #Draw a random graph with 10 members
closeness(g)        #Compute closeness scores
Description

James Coleman (1964) reports research on self-reported friendship ties among 73 boys in a small high school in Illinois over the 1957-1958 academic year. Networks of reported ties for all 73 informants are provided for two time points (fall and spring).

Usage

data(coleman)

Format

An adjacency array containing two directed, unvalued 73-node networks:

- \[1\] Fall binary matrix Friendship for Fall, 1957
- \[2\] Spring binary matrix Friendship for Spring, 1958

Details

Both networks reflect answers to the question, “What fellows here in school do you go around with most often?” with the presence of an \((i,j,k)\) edge indicating that \(j\) nominated \(k\) in time period \(i\). The data are unvalued and directed; although the self-reported ties are highly reciprocal, unreciprocated nominations are possible.

It should be noted that, although this data is usually described as “friendship,” the sociometric item employed might be more accurately characterized as eliciting “frequent elective interaction.” This should be borne in mind when interpreting this data.

component.dist     Calculate the Component Size Distribution of a Graph

Description

`component.dist` returns a list containing a vector of length \(n\) such that the \(i\)th element contains the number of components of graph \(G\) having size \(i\), and a vector of length \(n\) giving component membership (where \(n\) is the graph order). Component strength is determined by the `connected` parameter; see below for details.
**component.dist**

`component.dist()` identifies the component(s) of maximum order within graph `G`. It returns either a logical vector indicating membership in a maximum component or the adjacency matrix of the subgraph of `G` induced by the maximum component(s), as determined by `result`. Component strength is determined as per `component.dist`.

**Usage**

```r
component.dist(dat, connected=c("strong","weak","unilateral","recursive"))
```

```r
component.largest(dat, connected=c("strong","weak","unilateral","recursive"), result = c("membership", "graph"))
```

**Arguments**

- `dat`: one or more input graphs.
- `connected`: a string selecting strong, weak, unilateral or recursively connected components; by default, "strong" components are used.
- `result`: a string indicating whether a vector of membership indicators or the induced subgraph of the component should be returned.

**Details**

Components are maximal sets of mutually connected vertices; depending on the definition of "connected" one employs, one can arrive at several types of components. Those supported here are as follows (in increasing order of restrictiveness):

1. **weak**: \( v_1 \) is connected to \( v_2 \) iff there exists a semi-path from \( v_1 \) to \( v_2 \) (i.e., a path in the weakly symmetrized graph)
2. **unilateral**: \( v_1 \) is connected to \( v_2 \) iff there exists a directed path from \( v_1 \) to \( v_2 \) or a directed path from \( v_2 \) to \( v_1 \)
3. **strong**: \( v_1 \) is connected to \( v_2 \) iff there exists a directed path from \( v_1 \) to \( v_2 \) and a directed path from \( v_2 \) to \( v_1 \)
4. **recursive**: \( v_1 \) is connected to \( v_2 \) iff there exists a vertex sequence \( v_a, \ldots, v_z \) such that \( v_1, v_a, \ldots, v_z, v_2 \) and \( v_2, v_z, \ldots, v_a, v_1 \) are directed paths

Note that the above definitions are distinct for directed graphs only; if `dat` is symmetric, then the `connected` parameter has no effect.

**Value**

For `component.dist`, a list containing:

- **membership**: A vector of component memberships, by vertex
- **csize**: A vector of component sizes, by component
- **cdist**: A vector of length |V(G)| with the (unnormalized) empirical distribution function of component sizes

If multiple input graphs are given, the return value is a list of lists.

For `component.largest`, either a logical vector of component membership indicators or the adjacency matrix of the subgraph induced by the largest component(s) is returned. If multiple graphs were given as input, a list of results is returned.
Note

Unilaterally connected component partitions may not be well-defined, since it is possible for a given vertex to be unilaterally connected to two vertices which are not unilaterally connected with one another. Consider, for instance, the graph $a \rightarrow b \leftarrow c \rightarrow d$. In this case, the maximal unilateral components are $ab$ and $bcd$, with vertex $b$ properly belonging to both components. For such graphs, a unique partition of vertices by component does not exist, and we “solve” the problem by allocating each “problem vertex” to one of its components on an essentially arbitrary basis. (component.dist generates a warning when this occurs.) It is recommended that the unilateral option be avoided where possible.

Do not make the mistake of assuming that the subgraphs returned by component.largest are necessarily connected. This is usually the case, but depends upon the uniqueness of the largest component.

# Plot g, with component membership

gplot(g, vertex.col = 2 + lgc)  # Plot g, with component membership

# Plot largest component itself

gplot(component.largest(g, connected = "strong", result = "graph"))
```
**components**

*Find the Number of (Maximal) Components Within a Given Graph*

**Description**

Returns the number of components within `dat`, using the connectedness rule given in `connected`.

**Usage**

```r
components(dat, connected="strong", comp.dist.precomp=NULL)
```

**Arguments**

- `dat`: one or more input graphs.
- `connected`: the component definition to be used by `component.dist` during component extraction.
- `comp.dist.precomp`: a component size distribution object from `component.dist` (optional).

**Details**

The `connected` parameter corresponds to the `rule` parameter of `component.dist`. By default, `components` returns the number of strong components, but other component types can be returned if so desired. (See `component.dist` for details.) For symmetric matrices, this is obviously a moot point.

**Value**

A vector containing the number of components for each graph in `dat`

**Author(s)**

Carter T. Butts (buttsc@uci.edu)

**References**

components(g,connected="strong")
```
connectedness  

**Compute Graph Connectedness Scores**

**Description**

`connectedness` takes one or more graphs (`dat`) and returns the Krackhardt connectedness scores for the graphs selected by `g`.

**Usage**

```r
connectedness(dat, g=NULL)
```

**Arguments**

- `dat`  
  one or more graphs.

- `g`  
  index values for the graphs to be utilized; by default, all graphs are selected.

**Details**

Krackhardt’s connectedness for a digraph $G$ is equal to the fraction of all dyads, \{i, j\}, such that there exists an undirected path from $i$ to $j$ in $G$. (This, in turn, is just the density of the weak reachability graph of $G$.) Obviously, the connectedness score ranges from 0 (for the null graph) to 1 (for weakly connected graphs).

Connectedness is one of four measures (connectedness, efficiency, hierarchy, and lubness) suggested by Krackhardt for summarizing hierarchical structures. Each corresponds to one of four axioms which are necessary and sufficient for the structure in question to be an outtree; thus, the measures will be equal to 1 for a given graph iff that graph is an outtree. Deviations from unity can be interpreted in terms of failure to satisfy one or more of the outtree conditions, information which may be useful in classifying its structural properties.

**Value**

A vector containing the connectedness scores

**Note**

The four Krackhardt indices are, in general, nondegenerate for a relatively narrow band of size/density combinations (efficiency being the sole exception). This is primarily due to their dependence on the reachability graph, which tends to become complete rapidly as size/density increase. See Krackhardt (1994) for a useful simulation study.

```

---

### consensus

*Estimate a Consensus Structure from Multiple Observations*

**Description**

`consensus` estimates a central or consensus structure given multiple observations, using one of several algorithms.

**Usage**

```r
consensus(dat, mode="digraph", diag=FALSE, method="central.graph", tol=1e-06, maxiter=1e3, verbose=TRUE, no.bias=FALSE)
```

**Arguments**

- `dat`: a set of input graphs (must have same order).
- `mode`: "digraph" for directed data, else "graph".
- `diag`: logical; should diagonals (loops) be treated as data?
- `method`: one of "central.graph", "single.reweight", "iterative.reweight", "romney.batchelder", "PCA.reweight", "LAS.intersection", "LAS.union", "OR.row", or "OR.col".
- `tol`: convergence tolerance for the iterative reweighting and B-R algorithms.
- `maxiter`: maximum number of iterations to take (regardless of convergence) for the iterative reweighting and B-R algorithms.
- `verbose`: logical; should bias and competency parameters be reported (where computed)?
- `no.bias`: logical; should responses be assumed to be unbiased?

**Details**

The term “consensus structure” is used by a number of authors to reflect a notion of shared or common perceptions of social structure among a set of observers. As there are many interpretations of what is meant by “consensus” (and as to how best to estimate it), several algorithms are employed here:

1. `central.graph`: Estimate the consensus structure using the central graph. This corresponds to a “median response” notion of consensus.
2. `single.reweight`: Estimate the consensus structure using subject responses, reweighted by mean graph correlation. This corresponds to an “expertise-weighted vote” notion of consensus.
3. **iterative.reweight**: Similar to **single.reweight**, but the consensus structure and accuracy parameters are estimated via an iterated proportional fitting scheme. The implementation employed here uses both bias and competency parameters.

4. **romney.batchelder**: Fits a Romney-Batchelder informant accuracy model using IPF. This is very similar to **iterative.reweight**, but can be interpreted as the result of a process in which each informant report is correct with a probability equal to the informant’s competency score, and otherwise equal to a Bernoulli trial with parameter equal to the informant’s bias score.

5. **PCA.reweight**: Estimate the consensus using the (scores on the) first component of a network PCA. This corresponds to a “shared theme” or “common element” notion of consensus.

6. **LAS.intersection**: Estimate the consensus structure using the locally aggregated structure (intersection rule). In this model, an \( i \rightarrow j \) edge exists iff \( i \) and \( j \) agree that it exists.

7. **LAS.union**: Estimate the consensus structure using the locally aggregated structure (union rule). In this model, an \( i \rightarrow j \) edge exists iff \( i \) or \( j \) agree that it exists.

8. **OR.row**: Estimate the consensus structure using own report. Here, we take each informant’s outgoing tie reports to be correct.

9. **OR.col**: Estimate the consensus structure using own report. Here, we take each informant’s incoming tie reports to be correct.

Note that the results returned by the single weighting algorithms are not dichotomized by default; since some algorithms thus return valued graphs, dichotomization may be desirable prior to use.

It should be noted that a model for estimating an underlying criterion structure from multiple informant reports is provided in **bbnam**; if your goal is to reconstruct an “objective” network from informant reports, this (or the R-B model) may prove more useful than the ad-hoc solutions.

**Value**

An adjacency matrix representing the consensus structure

cug.test

Examples

```r
#Generate some test data
g<-rgraph(5)
g.pobs<-g*0.9+(1-g)*0.5
g.obs<-rgraph(5,5,tprob=g.pobs)

#Find some consensus structures
consensus(g.obs)          #Central graph
consensus(g.obs,method="single.reweight") #Single reweighting
consensus(g.obs,method="PCA.reweight")     #1st component in network PCA
```

cug.test

Univariate Conditional Uniform Graph Tests

Description

cug.test takes an input network and conducts a conditional uniform graph (CUG) test of the statistic in `FUN`, using the conditioning statistics in `cmode`. The resulting test object has custom print and plot methods.

Usage

cug.test(dat, FUN, mode = c("digraph", "graph"), cmode = c("size", "edges", "dyad.census"), diag = FALSE, reps = 1000, ignore.eval = TRUE, FUN.args = list())

Arguments

dat one or more input graphs.
FUN the function generating the test statistic; note that this must take a graph as its first argument, and return a single numerical value.
mode graph if dat is an undirected graph, else digraph.
cmode string indicating the type of conditioning to be applied.
diag logical; should self-ties be treated as valid data?
reps number of Monte Carlo replications to use.
ignore.eval logical; should edge values be ignored? (Note: TRUE is usually more efficient.)
FUN.args a list containing any additional arguments to FUN.

Details

cug.test is an improved version of cugtest, for use only with univariate CUG hypotheses. Depending on `cmode`, conditioning on the realized size, edge count (or exact edge value distribution), or dyad census (or dyad value distribution) can be selected. Edges are treated as unvalued unless `ignore.eval` = FALSE; since the latter setting is less efficient for sparse graphs, it should be used only when necessary.

A brief summary of the theory and goals of conditional uniform graph testing can be found in the reference below. See also cugtest for a somewhat informal description.
Value

An object of class `cug.test`.

cug.test(g, gtrans, cmode="edges")
cug.test(g, gtrans, cmode="dyad.census")
```

---

**cugtest**

Perform Conditional Uniform Graph (CUG) Hypothesis Tests for Graph-Level Indices

Description

cugtest tests an arbitrary GLI (computed on `dat` by `FUN`) against a conditional uniform graph null hypothesis, via Monte Carlo simulation. Some variation in the nature of the conditioning is available; currently, conditioning only on size, conditioning jointly on size and estimated tie probability (via expected density), and conditioning jointly on size and (bootstrapped) edge value distributions are implemented. Note that fair amount of flexibility is possible regarding CUG tests on functions of GLIs (Anderson et al., 1999). See below for more details.

Usage

cugtest(dat, FUN, reps=1000, gmode="digraph", cmode="density",
        diag=FALSE, g1=1, g2=2, ...)

Arguments

dat
graph(s) to be analyzed.

FUN
function to compute GLIs, or functions thereof. `FUN` must accept `dat` and the specified `g` arguments, and should return a real number.

reps
integer indicating the number of draws to use for quantile estimation. Note that, as for all Monte Carlo procedures, convergence is slower for more extreme quantiles. By default, `reps`=1000.
gmode
string indicating the type of graph being evaluated. "digraph" indicates that edges should be interpreted as directed; "graph" indicates that edges are undirected. gmode is set to "digraph" by default.

cmode
string indicating the type of conditioning assumed by the null hypothesis. If cmode is set to "density", then the density of the graph in question is used to determine the tie probabilities of the Bernoulli graph draws (which are also conditioned on |V(G)|). If cmode="ties", then draws are bootstrapped from the distribution of edge values within the data matrices. If cmode="order", then draws are uniform over all graphs of the same order (size) as the graphs within the input stack. By default, cmode is set to "density".

diag
boolean indicating whether or not the diagonal should be treated as valid data. Set this true if and only if the data can contain loops. diag is FALSE by default.

g1
integer indicating the index of the first graph input to the GLI. By default, g1=1.

g2
integer indicating the index of the second graph input to the GLI. (FUN can ignore this, if one wishes to test the GLI value of a single graph, but it should recognize the argument.) By default, g2=2.

... additional arguments to FUN.

Details
The null hypothesis of the CUG test is that the observed GLI (or function thereof) was drawn from a distribution equivalent to that of said GLI evaluated (uniformly) on the space of all graphs conditional on one or more features. The most common “features” used for conditioning purposes are order (size) and density, both of which are known to have strong and nontrivial effects on other GLIs (Anderson et al., 1999) and which are, in many cases, exogenously determined. (Note that maximum entropy distributions conditional on expected statistics are not in general correctly referred to as “conditional uniform graphs”, but have been described as such for independent-dyad models; this is indeed the case for this function, although such terminology is not really proper. See cug.test for CUG tests with exact conditioning.) Since theoretical results regarding functions of arbitrary GLIs on the space of graphs are not available, the standard approach to CUG testing is to approximate the quantiles of the observed statistic associated with the null hypothesis using Monte Carlo methods. This is the technique utilized by cugtest, which takes appropriately conditioned draws from the set of graphs and computes on them the GLI specified in FUN, thereby accumulating an approximation to the true quantiles.

The cugtest procedure returns a cugtest object containing the estimated distribution of the test GLI under the null hypothesis, the observed GLI value of the data, and the one-tailed p-values (estimated quantiles) associated with said observation. As usual, the (upper tail) null hypothesis is rejected for significance level alpha if p>=observation is less than alpha (or p<=observation, for the lower tail). Standard caveats regarding the use of null hypothesis testing procedures are relevant here: in particular, bear in mind that a significant result does not necessarily imply that the likelihood ratio of the null model and the alternative hypothesis favors the latter.

Informative and aesthetically pleasing portrayals of cugtest objects are available via the print.cugtest and summary.cugtest methods. The plot.cugtest method displays the estimated distribution, with a reference line signifying the observed value.

Value
An object of class cugtest, containing

testval The observed GLI value.
cutpoints

A vector containing the Monte Carlo draws.

The proportion of draws which were greater than or equal to the observed GLI value.

The proportion of draws which were less than or equal to the observed GLI value.

Note

This function currently conditions only on expected statistics, and is somewhat cumbersome. `cug.test` is now recommended for univariate CUG tests (and will eventually supplant this function).

Identify the Cutpoints of a Graph or Digraph

The `cutpoints` function identifies the cutpoints of an input graph. Depending on mode, either a directed or undirected notion of “cutpoint” can be used.

Usage

```r
cutpoints(dat, mode = "digraph", connected = c("strong","weak","recursive"),
          return.indicator = FALSE)
```
**cutpoints**

**Arguments**

- **dat**: one or more input graphs.
- **mode**: "digraph" for directed graphs, or "graph" for undirected graphs.
- **connected**: string indicating the type of connectedness rule to apply (only relevant where mode=="digraph").
- **return.indicator**: logical; should the results be returned as a logical (TRUE/FALSE) vector of indicators, rather than as a vector of vertex IDs?

**Details**

A **cutpoint** (also known as an **articulation point** or **cut-vertex**) of an undirected graph, \(G\) is a vertex whose removal increases the number of components of \(G\). Several generalizations to the directed case exist. Here, we define a **strong cutpoint** of directed graph \(G\) to be a vertex whose removal increases the number of strongly connected components of \(G\) (see `component.dist`). Likewise, **weak** and **recursive** cutpoints of \(G\) are those vertices whose removal increases the number of weak or recursive cutpoints (respectively). By default, strong cutpoints are used; alternatives may be selected via the **connected** argument.

Cutpoints are of particular interest when seeking to identify critical positions in flow networks, since their removal by definition alters the connectivity properties of the graph. In this context, cutpoint status can be thought of as a primitive form of centrality (with some similarities to `betweenness`).

Cutpoint computation is significantly faster for the undirected case (and for the weak/recursive cases) than for the strong directed case. While calling `cutpoints` with mode="digraph" on an undirected graph will give the same answer as mode="graph", it is thus to one’s advantage to use the latter form. Do not, however, employ mode="graph" with directed data, unless you enjoy unpredictable behavior.

**Value**

A vector of cutpoints (if `return.indicator==FALSE`), or else a logical vector indicating cutpoint status for each vertex.

**Degree**

Computes the Degree Centrality Scores of Network Positions

**Description**

Degree takes one or more graphs (dat) and returns the degree centralities of positions (selected by nodes) within the graphs indicated by g. Depending on the specified mode, indegree, outdegree, or total (Freeman) degree will be returned; this function is compatible with centralization, and will return the theoretical maximum absolute deviation (from maximum) conditional on size (which is used by centralization to normalize the observed centralization score).

**Usage**

```r
degree(dat, g=1, nodes=NULL, gmode="digraph", diag=FALSE,
       tmaxdev=FALSE, cmode="freeman", rescale=FALSE, ignore.eval=FALSE)
```

**Arguments**

- **dat**: one or more input graphs.
- **g**: integer indicating the index of the graph for which centralities are to be calculated (or a vector thereof). By default, g=1.
- **nodes**: vector indicating which nodes are to be included in the calculation. By default, all nodes are included.
- **gmode**: string indicating the type of graph being evaluated. "digraph" indicates that edges should be interpreted as directed; "graph" indicates that edges are undirected. gmode is set to "digraph" by default.
- **diag**: boolean indicating whether or not the diagonal should be treated as valid data. Set this true if and only if the data can contain loops. diag is FALSE by default.
- **tmaxdev**: boolean indicating whether or not the theoretical maximum absolute deviation from the maximum nodal centrality should be returned. By default, tmaxdev=FALSE.
- **cmode**: string indicating the type of degree centrality being computed. "indegree", "outdegree", and "freeman" refer to the indegree, outdegree, and total (Freeman) degree measures, respectively. The default for cmode is "freeman".
- **rescale**: if true, centrality scores are rescaled such that they sum to 1.
- **ignore.eval**: logical; should edge values be ignored when computing degree scores?
Details

Degree centrality is the social networker’s term for various permutations of the graph theoretic notion of vertex degree: for unvalued graphs, indegree of a vertex, \( v \), corresponds to the cardinality of the vertex set \( N^+(v) = \{ i \in V(G) : (i, v) \in E(G) \} \); outdegree corresponds to the cardinality of the vertex set \( N^-(v) = \{ i \in V(G) : (v, i) \in E(G) \} \); and total (or “Freeman”) degree corresponds to \( |N^+(v)| + |N^-(v)| \). (Note that, for simple graphs, indegree=outdegree=total degree/2.) Obviously, degree centrality can be interpreted in terms of the sizes of actors’ neighborhoods within the larger structure. See the references below for more details.

When \( \text{ignore.eval==FALSE} \), degree weights edges by their values where supplied. \( \text{ignore.eval==TRUE} \) ensures an unweighted degree score (independent of input). Setting \( \text{gmode=="graph"} \) forces behavior equivalent to \( \text{cmode=="indegree"} \) (i.e., each edge is counted only once); to obtain a total degree score for an undirected graph in which both in- and out-neighborhoods are counted separately, simply use \( \text{gmode=="digraph"} \).

Value

A vector, matrix, or list containing the degree scores (depending on the number and size of the input graphs).

---

diag.remove

Remove the Diagonals of Adjacency Matrices in a Graph Stack

Description

Returns the input graphs, with the diagonal entries removed/replaced as indicated.

Usage

diag.remove(dat, remove.val=NA)
Arguments

- **dat**: one or more graphs.
- **remove.val**: the value with which to replace the existing diagonals

Details

diag.remove is simply a convenient way to apply `diag` to an entire collection of adjacency matrices/network objects at once.

Value

The updated graphs.

Author(s)

Carter T. Butts (buttsc@uci.edu)

```r
# Generate a random graph stack
g <- rgraph(3, 5)
# Remove the diagonals
g <- diag.remove(g)
```

---

**dyad.census**  
Compute a Holland and Leinhardt MAN Dyad Census

Description

`dyad.census` computes a Holland and Leinhardt dyad census on the graphs of `dat` selected by `g`.

Usage

```r
dyad.census(dat, g=NULL)
```

Arguments

- **dat**: one or more graphs.
- **g**: the elements of `dat` to be included; by default, all graphs are processed.
Details

Each dyad in a directed graph may be in one of four states: the null state \((a \not\leftrightarrow b)\), the complete or mutual state \((a \leftrightarrow b)\), and either of two asymmetric states \((a \leftarrow b)\) or \((a \rightarrow b)\). Holland and Leinhardt’s dyad census classifies each dyad into the mutual, asymmetric, or null categories, counting the number of each within the digraph. These counts can be used as the basis for null hypothesis tests (since their distributions are known under assumptions such as constant edge probability), or for the generation of random graphs (e.g., via the U\(\text{M\text{A\text{N}}}\) distribution, which conditions on the numbers of mutual, asymmetric, and null dyads in each graph).

Value

A matrix whose three columns contain the counts of mutual, asymmetric, and null dyads (respectively) for each graph

Author(s)

---

efficiency  
Compute Graph Efficiency Scores

Description

{\texttt{efficiency}} takes one or more graphs \texttt{(dat)} and returns the Krackhardt efficiency scores for the graphs selected by \texttt{g}.

Usage

{\texttt{efficiency}}(\texttt{dat, g=NULL, diag=FALSE})

Arguments

dat  one or more graphs.

g  index values for the graphs to be utilized; by default, all graphs are selected.

diag  TRUE if the diagonal contains valid data; by default, \texttt{diag==FALSE}.
Let $G = \bigcup_{i=1}^{n} G_i$ be a digraph with weak components $G_1, G_2, \ldots, G_n$. For convenience, we denote the cardinalities of these components’ vertex sets by $|V(G)| = N$ and $|V(G_i)| = N_i$, $\forall i \in 1, \ldots, n$. Then the Krackhardt efficiency of $G$ is given by

$$1 - \frac{|E(G)| - \sum_{i=1}^{n} (N_i - 1)}{\sum_{i=1}^{n} (N_i (N_i - 1) - (N_i - 1))}$$

which can be interpreted as 1 minus the proportion of possible “extra” edges (above those needed to weakly connect the existing components) actually present in the graph. A graph which an efficiency of 1 has precisely as many edges as are needed to connect its components; as additional edges are added, efficiency gradually falls towards 0.

Efficiency is one of four measures (connectedness, efficiency, hierarchy, and lubness) suggested by Krackhardt for summarizing hierarchical structures. Each corresponds to one of four axioms which are necessary and sufficient for the structure in question to be an outtree; thus, the measures will be equal to 1 for a given graph iff that graph is an outtree. Deviations from unity can be interpreted in terms of failure to satisfy one or more of the outtree conditions, information which may be useful in classifying its structural properties.

**Value**

A vector of efficiency scores

**Note**

The four Krackhardt indices are, in general, nondegenerate for a relatively narrow band of size/density combinations (efficiency being the sole exception). This is primarily due to their dependence on the reachability graph, which tends to become complete rapidly as size/density increase. See Krackhardt (1994) for a useful simulation study.

The violation normalization used before version 0.51 was $N (N - 1) \sum_{i=1}^{n} (N_i - 1)$, based on a somewhat different interpretation of the definition in Krackhardt (1994). The former version gave results which more closely matched those of the cited simulation study, but was less consistent with the textual definition.

```
ego.extract  

Extract Egocentric Networks from Complete Network Data

Description

ego.extract takes one or more input graphs (dat) and returns a list containing the egocentric networks centered on vertices named in ego, using adjacency rule neighborhood to define inclusion.

Usage

ego.extract(dat, ego = NULL, neighborhood = c("combined", "in", "out"))

Arguments

dat  one or more graphs.

ego  a vector of vertex IDs, or NULL if all are to be selected.

neighborhood  the neighborhood to use.

Details

The egocentric network (or "ego net") of vertex \(v\) in graph \(G\) is defined as \(G[v \cup N(v)]\) (i.e., the subgraph of \(G\) induced by \(v\) and its neighborhood). The neighborhood employed by ego.extract is selected by the eponymous argument: "in" selects in-neighbors, "out" selects out-neighbors, and "combined" selects all neighbors. In the event that one of the vertices selected by ego has no qualifying neighbors, ego.extract will return a degenerate (1 by 1) adjacency matrix containing that individual's diagonal entry.

Vertices within the returned matrices are maintained in their original order, save for ego (who is always listed first). The ego nets themselves are returned in the order specified in the ego parameter (or their vertex order, if no value was specified).

ego.extract is useful for finding local properties associated with particular vertices. To compute functions of neighbors' covariates, see gapply.

Value

A list containing the adjacency matrices for the ego nets of each vertex in ego.

Author(s)

Carter T. Butts (buttc@uci.edu)

g.out <- ego.extract(g, neighborhood="out")
g.comb <- ego.extract(g, neighborhood="in")

# View some networks
g.comb

# Compare ego net size with degree
all(sapply(g.in, NROW) == degree(g, cmode="indegree") + 1)  # TRUE
all(sapply(g.out, NROW) == degree(g, cmode="outdegree") + 1)  # TRUE
all(sapply(g.comb, NROW) == degree(g) / 2 + 1)  # Usually FALSE!

# Calculate egocentric network density
ego.size <- sapply(g.comb, NROW)
if (any(ego.size > 2))
  sapply(g.comb[ego.size > 2], function(x) {gden(x[-1,-1])})

equiv.clust

Find Clusters of Positions Based on an Equivalence Relation

description

equiv.clust uses a definition of approximate equivalence (equiv.fun) to form a hierarchical clustering of network positions. Where dat consists of multiple relations, all specified relations are considered jointly in forming the equivalence clustering.

Usage

equiv.clust(dat, g=NULL, equiv.dist=NULL, equiv.fun="sedist",
method="hamming", mode="digraph", diag=FALSE,
cluster.method="complete", glabels=NULL, plabels=NULL, ...)

Arguments

dat one or more graphs.
g the elements of dat to use in clustering the vertices; by default, all structures are used.
equiv.dist a matrix of distances, by which vertices should be clustered. (Overrides equiv.fun.)
equiv.fun the distance function to use in clustering vertices (defaults to sedist).
method method parameter to be passed to equiv.fun.
mode "graph" or "digraph," as appropriate.
diag a boolean indicating whether or not matrix diagonals (loops) should be interpreted as useful data.
cluster.method the hierarchical clustering method to use (see hclust).
equiv.clust

glabels labels for the various graphs in dat.
plabels labels for the vertices of dat.
... additional arguments to equiv.dist.

Details

This routine is essentially a joint front-end to hclust and various positional distance functions, though it defaults to structural equivalence in particular. Taking the specified graphs as input, equiv.clust computes the distances between all pairs of positions using equiv.fun (unless distances are supplied in equiv.dist), and then performs a cluster analysis of the result. The return value is an object of class equiv.clust, for which various secondary analysis methods exist.

Value

An object of class equiv.clust

Note

See sedist for an example of a distance function compatible with equiv.clust.

#Cluster based on structural equivalence
eq<-equiv.clust(g)
plot(eq)
eval.edgeperturbation

Compute the Effects of Single-Edge Perturbations on Structural Indices

Description
Evaluates a given function on an input graph with and without a specified edge, returning the difference between the results in each case.

Usage
eval.edgeperturbation(dat, i, j, FUN, ...)

Arguments
dat            A single adjacency matrix
i              The row(s) of the edge(s) to be perturbed
j              The column(s) of the edge(s) to be perturbed
FUN            The function to be computed
...            Additional arguments to FUN

Details
Although primarily a back-end utility for pstar, eval.edgeperturbation may be useful in any circumstance in which one wishes to assess the stability of a given structural index with respect to single edge perturbations. The function to be evaluated is calculated first on the input graph with all marked edges set to present, and then on the same graph with said edges absent. (Obviously, this is sensible only for dichotomous data.) The difference is then returned.

In pstar, calls to eval.edgeperturbation are used to construct a perturbation effect matrix for the GLM.

Value
The difference in the values of FUN as computed on the perturbed graphs.

Note
length(i) and length(j) must be equal; where multiple edges are specified, the row and column listings are interpreted as pairs.

# How much does a one-edge change affect reciprocity?
eval.edgeperturbation(g,1,2,grecip)

evcent

Find Eigenvector Centrality Scores of Network Positions

Description

evcent takes one or more graphs (dat) and returns the eigenvector centralities of positions (selected by nodes) within the graphs indicated by g. This function is compatible with centralization, and will return the theoretical maximum absolute deviation (from maximum) conditional on size (which is used by centralization to normalize the observed centralization score).

Usage

```
evcent(dat, g=1, nodes=NULL, gmode="digraph", diag=FALSE,
        tmaxdev=FALSE, rescale=FALSE, ignore.eval=FALSE, tol=1e-10)
```

Arguments

dat one or more input graphs.
g integer indicating the index of the graph for which centralities are to be calculated (or a vector thereof). By default, g=1.
nodes vector indicating which nodes are to be included in the calculation. By default, all nodes are included.
gmode string indicating the type of graph being evaluated. "digraph" indicates that edges should be interpreted as directed; "graph" indicates that edges are undirected. This is currently ignored.
diag boolean indicating whether or not the diagonal should be treated as valid data. Set this true if and only if the data can contain loops. diag is FALSE by default.
tmaxdev boolean indicating whether or not the theoretical maximum absolute deviation from the maximum nodal centrality should be returned. By default, tmaxdev=FALSE.
rescale if true, centrality scores are rescaled such that they sum to 1.
ignore.eval logical; should edge values be ignored?
tol convergence tolerance for the eigenvector computation.
Eigenvector centrality scores correspond to the values of the first eigenvector of the graph adjacency matrix; these scores may, in turn, be interpreted as arising from a reciprocal process in which the centrality of each actor is proportional to the sum of the centralities of those actors to whom he or she is connected. In general, vertices with high eigenvector centralities are those which are connected to many other vertices which are, in turn, connected to many others (and so on). (The perceptive may realize that this implies that the largest values will be obtained by individuals in large cliques (or high-density substructures). This is also intelligible from an algebraic point of view, with the first eigenvector being closely related to the best rank-1 approximation of the adjacency matrix (a relationship which is easy to see in the special case of a diagonalizable symmetric real matrix via the $S \Lambda S^{-1}$ decomposition).)

The simple eigenvector centrality is generalized by the Bonacich power centrality measure; see `bonpow` for more details.

A vector, matrix, or list containing the centrality scores (depending on the number and size of the input graphs).

**WARNING**

`evcent` will not symmetrize your data before extracting eigenvectors; don’t send this routine asymmetric matrices unless you really mean to do so.

The theoretical maximum deviation used here is not obtained with the star network, in general. For symmetric data, the maximum occurs for an empty graph with one complete dyad; the maximum deviation for asymmetric data is generated by the outstar. UCINET V seems not to adjust for this fact, which can cause some oddities in their centralization scores (and results in a discrepancy in centralizations between the two packages).

Carter T. Butts (buttsc@uci.edu)

#Generate some test data
dat<-rgraph(10,mode="graph")
#Compute eigenvector centrality scores
evcent(dat)
```
Convert an Observed Event Matrix to a Dichotomous matrix

Description

Given one or more valued adjacency matrices (possibly derived from observed interaction “events”), `event2dichot` returns dichotomized equivalents.

Usage

```
event2dichot(m, method="quantile", thresh=0.5, leq=FALSE)
```

Arguments

- `m`: one or more (valued) input graphs.
- `method`: one of “quantile,” “rquantile,” “cquantile,” “mean,” “rmean,” “cmean,” “absolute,” “rank,” “rrank,” or “crank”.
- `thresh`: dichotomization thresholds for ranks or quantiles.
- `leq`: boolean indicating whether values less than or equal to the threshold should be taken as existing edges; the alternative is to use values strictly greater than the threshold.

Details

The methods used for choosing dichotomization thresholds are as follows:

1. quantile: specified quantile over the distribution of all edge values
2. rquantile: specified quantile by row
3. cquantile: specified quantile by column
4. mean: grand mean
5. rmean: row mean
6. cmean: column mean
7. absolute: the value of `thresh` itself
8. rank: specified rank over the distribution of all edge values
9. rrank: specified rank by row
10. crank: specified rank by column

Note that when a quantile, rank, or value is said to be “specified,” this refers to the value of `thresh`.

Value

The dichotomized data matrix (or matrices)

Author(s)

Carter T. Butts (buttsc@uci.edu)
References

Examples

# Draw a matrix of normal values
n <- matrix(rnorm(25), nrow=5, ncol=5)

# Dichotomize by the mean value

# Dichotomize by the 0.95 quantile
event2dichot(n,"quantile",0.95)

---

flowbet: Calculate Flow Betweenness Scores of Network Positions

Description

flowbet takes one or more graphs (dat) and returns the flow betweenness scores of positions (selected by nodes) within the graphs indicated by g. Depending on the specified mode, flow betweenness on directed or undirected geodesics will be returned; this function is compatible with centralization, and will return the theoretical maximum absolute deviation (from maximum) conditional on size (which is used by centralization to normalize the observed centralization score).

Usage

flowbet(dat, g = 1, nodes = NULL, gmode = "digraph", diag = FALSE, tmaxdev = FALSE, cmode = "rawflow", rescale = FALSE, ignore.eval = FALSE)

Arguments

dat one or more input graphs.
g integer indicating the index of the graph for which centralities are to be calculated (or a vector thereof). By default, g=1.
nodes vector indicating which nodes are to be included in the calculation. By default, all nodes are included.
gmode string indicating the type of graph being evaluated. digraph indicates that edges should be interpreted as directed (with flows summed over directed dyads); graph indicates that edges are undirected (with only undirected pairs considered). gmode is set to digraph by default.
diag boolean indicating whether or not the diagonal should be treated as valid data. Set this true if and only if the data can contain loops. diag is FALSE by default.
tmaxdev boolean indicating whether or not the theoretical maximum absolute deviation from the maximum nodal centrality should be returned. By default, tmaxdev==FALSE.
cmode one of rawflow, normflow, or fracflow (see below).
The ("raw," or unnormalized) flow betweenness of a vertex, \( v \in V(G) \), is defined by Freeman et al. (1991) as

\[
C_F(v) = \sum_{i,j: i \neq j, i \neq v, j \neq v} (f(i, j, G) - f(i, j, G \setminus v)),
\]

where \( f(i, j, G) \) is the maximum flow from \( i \) to \( j \) within \( G \) (under the assumption of infinite vertex capacities, finite edge capacities, and non-simultaneity of pairwise flows). Intuitively, unnormalized flow betweenness is simply the total maximum flow (aggregated across all pairs of third parties) mediated by \( v \).

The above flow betweenness measure is computed by flowbet when \( \text{cmode}=="\text{rawflow}" \). In some cases, it may be desirable to normalize the raw flow betweenness by the total maximum flow among third parties (including \( v \)); this leads to the following normalized flow betweenness measure:

\[
C'_F(v) = \frac{\sum_{i,j: i \neq j, i \neq v, j \neq v} (f(i, j, G) - f(i, j, G \setminus v))}{\sum_{i,j: i \neq j, i \neq v, j \neq v} f(i, j, G)}.
\]

This variant can be selected by setting \( \text{cmode}=="\text{normflow}" \).

Finally, it may be noted that the above normalization (from Freeman et al. (1991)) is rather different from that used in the definition of shortest-path betweenness, which normalizes within (rather than across) third-party dyads. A third flow betweenness variant has been suggested by Koschutzki et al. (2005) based on a normalization of this type:

\[
C''_F(v) = \frac{\sum_{i,j: i \neq j, i \neq v, j \neq v} (f(i, j, G) - f(i, j, G \setminus v))}{f(i, j, G)}
\]

where 0/0 flow ratios are treated as 0 (as in shortest-path betweenness). Setting \( \text{cmode}=="\text{fracflow}" \) selects this variant.

**Value**

A vector of centrality scores.

# Raw flow betweenness
flowbet(g)

# Normalized flow betweenness
flowbet(g, cmode = "normflow")

# Add capacity constraints

# Note the difference!
g <- g * matrix(rpois(100, 4), 10, 10)

# Draw a random graph
flowbet(g)
```

---

**gapply**

*Apply Functions Over Vertex Neighborhoods*

**Description**

Returns a vector or array or list of values obtained by applying a function to vertex neighborhoods of a given order.

**Usage**

```r
gapply(X, MARGIN, STATS, FUN, ..., mode = "digraph", diag = FALSE, distance = 1, thresh = 0, simplify = TRUE)
```

**Arguments**

- `X`: one or more input graphs.
- `MARGIN`: a vector giving the “margin” of `X` to be used in calculating neighborhoods. 1 indicates rows (out-neighbors), 2 indicates columns (in-neighbors), and c(1,2) indicates rows and columns (total neighborhood).
- `STATS`: the vector or matrix of vertex statistics to be used.
- `FUN`: the function to be applied. In the case of operators, the function name must be quoted.
- `...`: additional arguments to `FUN`.
- `mode`: "graph" if `X` is a simple graph, else "digraph".
- `diag`: boolean; are the diagonals of `X` meaningful?
- `distance`: the maximum geodesic distance at which neighborhoods are to be taken. 1 signifies first-order neighborhoods, 2 signifies second-order neighborhoods, etc.
- `thresh`: the threshold to be used in dichotomizing `X`.
- `simplify`: boolean; should we attempt to coerce output to a vector if possible?

**Details**

For each vertex in `X`, `gapply` first identifies all members of the relevant neighborhood (as determined by `MARGIN` and `distance`) and pulls the rows of `STATS` associated with each. `FUN` is then applied to this collection of values. This provides a very quick and easy way to answer questions like:

- How many persons are in each ego’s 3rd-order neighborhood?
- What fraction of each ego’s alters are female?
- What is the mean income for each ego’s trading partners?
- etc.

With clever use of `FUN` and `STATS`, a wide range of functionality can be obtained.
**gclust.boxstats**

**Value**

The result of the iterated application of `FUN` to each vertex neighborhood’s `STATS`.

**Author(s)**

Carter T. Butts ⟨buttsc@uci.edu⟩

**See Also**

apply, sapply

**Examples**

```r
#Generate a random graph
g<-rgraph(6)

#Calculate the degree of g using gapply
all(gapply(g,1,rep(1,6),sum)==degree(g,cmode="outdegree"))
all(gapply(g,2,rep(1,6),sum)==degree(g,cmode="indegree"))
all(gapply(g,c(1,2),rep(1,6),sum)==degree(symmetrize(g),cmode="freeman")/2)

#Find first and second order neighborhood means on some variable
gapply(g,c(1,2),1:6,mean)
gapply(g,c(1,2),1:6,mean,distance=2)
```

---

**gclust.boxstats**  
*Plot Statistics Associated with Graph Clusters*

**Description**

gclust.boxstats creates side-by-side boxplots of graph statistics based on a hierarchical clustering of networks (cut into k sets).

**Usage**

gclust.boxstats(h, k, meas, ...)

**Arguments**

- `h`  
an `hclus` object, presumably formed by clustering a set of structural distances.
- `k`  
the number of groups to evaluate.
- `meas`  
a vector of length equal to the number of graphs in `h`, containing a GLI to be evaluated.
- `...`  
additional parameters to `boxplot`.

**Details**

gclust.boxstats simply takes the `hclus` object in `h`, applies `cutree` to form `k` groups, and then uses `boxplot` on the distribution of `meas` by group. This can be quite handy for assessing graph clusters.
Value
None

Note
Actually, this function will work with any \texttt{hclust} object and measure matrix; the data need not originate with social networks. For this reason, the clever may also employ this function in conjunction with \texttt{sdist} or \texttt{equiv.clust} to plot NLIs against clusters of positions within a graph.

#Create some random graphs
g<-rgraph(10,20,tprob=c(rbeta(10,15,2),rbeta(10,2,15)))

#Find the Hamming distances between them
g,h<-hdist(g)

#Cluster the graphs via their Hamming distances
g.c<-hclust(as.dist(g,h))

#Now display boxplots of density by cluster for a two cluster solution
gclust.boxstats(g.c,2,gden(g))
\end{verbatim}

---

\texttt{gclust.centralgraph}

Get Central Graphs Associated with Graph Clusters

Description
Calculates central graphs associated with particular graph clusters (as indicated by the $k$ partition of $h$).

Usage
\texttt{gclust.centralgraph(h, k, dat, ...)}
Arguments

h  an hclust object, based on a graph stack in dat.

k  the number of groups to evaluate.

dat  one or more graphs (on which the clustering was performed).

...  additional arguments to centralgraph.

Details

gclust.centralgraph uses cutree to cut the hierarchical clustering in h into k groups. centralgraph is then called on each cluster, and the results are returned as a graph stack. This is a useful tool for interpreting clusters of (labeled) graphs, with the resulting central graphs being subsequently analyzed using standard SNA methods.

Value

An array containing the stack of central graph adjacency matrices

Author(s)

Carter T. Butts 〈butsc@uci.edu〉

g<-rgraph(10,20,tprob=c(rbeta(10,15,2),rbeta(10,2,15)))

#Find the Hamming distances between them

g.h<-hdist(g)

#Cluster the graphs via their Hamming distances

g.c<-hclust(as.dist(g.h))

#Now find central graphs by cluster for a two cluster solution

g.cg<-gclust.centralgraph(g.c,2,g)

#Plot the central graphs

gplot(g.cg[1,1])
gplot(g.cg[2,1])
**gcor**  
*Find the (Product-Moment) Correlation Between Two or More Labeled Graphs*

**Description**

`gcor` finds the product-moment correlation between the adjacency matrices of graphs indicated by `g1` and `g2` in stack `dat` (or possibly `dat2`). Missing values are permitted.

**Usage**

```r
gcor(dat, dat2=NULL, g1=NULL, g2=NULL, diag=FALSE, mode="digraph")
```

**Arguments**

- `dat` one or more input graphs.
- `dat2` optionally, a second stack of graphs.
- `g1` the indices of `dat` reflecting the first set of graphs to be compared; by default, all members of `dat` are included.
- `g2` the indices of `dat` (or `dat2`, if applicable) reflecting the second set of graphs to be compared; by default, all members of `dat` are included.
- `diag` boolean indicating whether or not the diagonal should be treated as valid data. Set this true if and only if the data can contain loops. `diag` is `FALSE` by default.
- `mode` string indicating the type of graph being evaluated. "Digraph" indicates that edges should be interpreted as directed; "graph" indicates that edges are undirected. `mode` is set to "digraph" by default.

**Details**

The (product moment) graph correlation between labeled graphs `G` and `H` is given by

$$
cor(G, H) = \frac{cov(G, H)}{\sqrt{cov(G, G) cov(H, H)}}
$$

where the graph covariance is defined as

$$
cov(G, H) = \frac{1}{(|V|)^2} \sum_{i,j} (A_{ij}^G - \mu_G) (A_{ij}^H - \mu_H)
$$

(with $A^G$ being the adjacency matrix of $G$). The graph correlation/covariance is at the center of a number of graph comparison methods, including network variants of regression analysis, PCA, CCA, and the like.

Note that `gcor` computes only the correlation between *uniquely labeled* graphs. For the more general case, `gscor` is recommended.

**Value**

A graph correlation matrix
Note

The \texttt{gcor} routine is really just a front-end to the standard \texttt{cor} method; the primary value-added is the transparent vectorization of the input graphs (with intelligent handling of simple versus directed graphs, diagonals, etc.). As noted, the correlation coefficient returned is a standard Pearson’s product-moment coefficient, and output should be interpreted accordingly. Classical null hypothesis testing procedures are not recommended for use with graph correlations; for nonparametric null hypothesis testing regarding graph correlations, see \texttt{cugtest} and \texttt{qaptest}. For multivariate correlations among graph sets, try \texttt{netcancor}.

Author(s)
Carter T. Butts (butts@uci.edu)

References

\texttt{gscor, gcov, gscov}

Examples

```r
#Generate two random graphs each of low, medium, and high density
g <- rgraph(10, 6, tprob = c(0.2, 0.2, 0.5, 0.5, 0.8, 0.8))

#Examine the correlation matrix
gcor(g)
```

\textbf{gcov}

\textit{Find the Covariance(s) Between Two or More Labeled Graphs}

\textbf{Description}

\texttt{gcov} finds the covariances between the adjacency matrices of graphs indicated by \texttt{g1} and \texttt{g2} in stack \texttt{dat} (or possibly \texttt{dat2}). Missing values are permitted.

\textbf{Usage}

\texttt{gcov(dat, dat2=NULL, g1=NULL, g2=NULL, diag=FALSE, mode="digraph")}

\textbf{Arguments}

- \texttt{dat} one or more input graphs.
- \texttt{dat2} optionally, a second graph stack.
- \texttt{g1} the indices of \texttt{dat} reflecting the first set of graphs to be compared; by default, all members of \texttt{dat} are included.
- \texttt{g2} the indices or \texttt{dat} (or \texttt{dat2}, if applicable) reflecting the second set of graphs to be compared; by default, all members of \texttt{dat} are included.
**Details**

The graph covariance between two labeled graphs is defined as

\[
cov(G, H) = \frac{1}{\binom{|V|}{2}} \sum_{i,j} (A_{ij}^G - \mu_G) (A_{ij}^H - \mu_H)
\]

(with \(A^G\) being the adjacency matrix of \(G\)). The graph correlation/covariance is at the center of a number of graph comparison methods, including network variants of regression analysis, PCA, CCA, and the like.

Note that `gcov` computes only the covariance between uniquely labeled graphs. For the more general case, `gscov` is recommended.

**Value**

A graph covariance matrix

**Note**

The `gcov` routine is really just a front-end to the standard `cov` method; the primary value-added is the transparent vectorization of the input graphs (with intelligent handling of simple versus directed graphs, diagonals, etc.). Classical null hypothesis testing procedures are not recommended for use with graph covariance; for nonparametric null hypothesis testing regarding graph covariance, see `cugtest` and `qaptest`.

# Examine the covariance matrix
gcov(g)
```
Description

gden computes the density of the graphs indicated by \texttt{g} in collection \texttt{dat}, adjusting for the type of graph in question.

Usage

gden(dat, g=NULL, diag=FALSE, mode="digraph", ignore.eval=FALSE)

Arguments

dat one or more input graphs.
g integer indicating the index of the graphs for which the density is to be calculated (or a vector thereof). If \texttt{g==NULL} (the default), density is calculated for all graphs in \texttt{dat}.
diag boolean indicating whether or not the diagonal should be treated as valid data. Set this true if and only if the data can contain loops. \texttt{diag} is \texttt{FALSE} by default.
mode string indicating the type of graph being evaluated. "digraph" indicates that edges should be interpreted as directed; "graph" indicates that edges are undirected. \texttt{mode} is set to "digraph" by default.
ignore.eval logical; should edge values be ignored when calculating density?

Details

The density of a graph is here taken to be the sum of tie values divided by the number of possible ties (i.e., an unbiased estimator of the graph mean); hence, the result is interpretable for valued graphs as the mean tie value when \texttt{ignore.eval==FALSE}. The number of possible ties is determined by the graph type (and by \texttt{diag}) in the usual fashion.

Value

The graph density

Examples

# Draw three random graphs
dat<-rgraph(10,3)
# Find their densities
gden(dat)
gdist.plotdiff

Plot Differences in Graph-level Statistics Against Inter-graph Distances

Description

For a given graph set, gdist.plotdiff plots the distances between graphs against their distances (or differences) on a set of graph-level measures.

Usage

```r
gdist.plotdiff(d, meas, method="manhattan", jitter=TRUE, xlab="Inter-Graph Distance", ylab="Measure Distance", lm.line=FALSE, ...)
```

Arguments

d A matrix containing the inter-graph distances
meas An n x m matrix containing the graph-level indices; rows of this matrix must correspond to graphs, and columns to indices
method The distance method used by `dist` to establish differences/distances between graph GLI values. By default, absolute ("manhattan") differences are used.
jitter Should values be jittered prior to display?
xlab A label for the X axis
ylab A label for the Y axis
lm.line Include a least-squares line?
... Additional arguments to `plot`

Details

gdist.plotdiff works by taking the distances between all graphs on `meas` and then plotting these distances against `d` for all pairs of graphs (with, optionally, an added least-squares line for reference value). This can be a useful exploratory tool for relating inter-graph distances (e.g., Hamming distances) to differences on other attributes.

Value

None

Note

This function is actually quite generic, and can be used with node-level – or even non-network – data as well.

Carter T. Butts (buttsc@uci.edu)
gdist.plotstats

Plot Various Graph Statistics Over a Network MDS

Description

Plots a two-dimensional metric MDS of d, with the corresponding values of meas indicated at each point. Various options are available for controlling how meas is to be displayed.

Usage

gdist.plotstats(d, meas, siz.lim=c(0, 0.15), rescale="quantile", display.scale="radius", display.type="circleray", cex=0.5, pch=1, labels=NULL, pos=1, labels.cex=1, legend=NULL, legend.xy=NULL, legend.cex=1, ...)

Arguments

d A matrix containing the inter-graph distances
meas An nxm matrix containing the graph-level measures; each row must correspond to a graph, and each column must correspond to an index
siz.lim The minimum and maximum sizes (respectively) of the plotted symbols, given as fractions of the total plotting range
rescale One of “quantile” for ordinal scaling, “affine” for max-min scaling, and “normalize” for rescaling by maximum value; these determine the scaling rule to be used in sizing the plotting symbols
display.scale One of “area” or “radius”; this controls the attribute of the plotting symbol which is rescaled by the value of meas
display.type One of “circle”, “ray”, “circleray”, “poly”, or “polyray”; this determines the type of plotting symbol used (circles, rays, polygons, or some combination of these)
gdist.plotstats

Details

gdist.plotstats works by performing an MDS (using cmdscale) on d, and then using the values in meas to determine the shape of the points at each MDS coordinate. Typically, these shapes involve rays of varying color and length indicating meas magnitude, with circles and polygons of the appropriate radius and/or error being options as well. Various options are available (described above) to govern the details of the data display; some tinkering may be needed in order to produce an aesthetically pleasing visualization.

The primary use of gdist.plotstats is to explore broad relationships between graph properties and inter-graph distances. This routine complements others in the gdist and gclust family of interstructural visualization tools.

Value

None

Note

This routine does not actually depend on the data’s being graphic in origin, and can be used with any distance matrix/measure matrix combination.

Examples

```r
# Generate random graphs with varying density
g <- rgraph(10, 20, tprob = runif(20, 0, 1))

# Get Hamming distances between graphs
g.h <- hdist(g)

# Plot the association of distance, density, and reciprocity
gdist.plot.stats(g.h, cbind(gden(g), grecip(g)))
```

description

**geodist** uses a BFS to find the number and lengths of geodesics between all nodes of `dat`. Where geodesics do not exist, the value in `inf.replace` is substituted for the distance in question.

**Usage**

```r
geodist(dat, inf.replace = Inf, count.paths = TRUE, predecessors = FALSE, ignore.eval = TRUE)
```

**Arguments**

- `dat`: one or more input graphs.
- `inf.replace`: the value to use for geodesic distances between disconnected nodes; by default, this is equal Inf.
- `count.paths`: logical; should a count of geodesics be included in the returned object?
- `predecessors`: logical; should a predecessor list be included in the returned object?
- `ignore.eval`: logical; should edge values be ignored when computing geodesics?

**Details**

This routine is used by a variety of other functions; many of these will allow the user to provide manually precomputed `geodist` output so as to prevent expensive recomputation. Note that the choice of infinite path length for disconnected vertex pairs is non-canonical (albeit common), and some may prefer to simply treat these as missing values. `geodist` (without loss of generality) treats all paths as directed, a fact which should be kept in mind when interpreting `geodist` output.

By default, `geodist` ignores edge values. Setting `ignore.eval = FALSE` will change this behavior, with edge values being interpreted as distances; where edge values reflect proximity or tie strength, transformation may be necessary. Edge values should also be non-negative. Because the valued-case algorithm is significantly slower than the unvalued-case algorithm, `ignore.eval` should be set to TRUE wherever possible.
gliop

Value

A list containing:

- `counts`: If `count.paths==TRUE`, a matrix containing the number of geodesics between each pair of vertices.
- `sigma`: A matrix containing the geodesic distances between each pair of vertices.
- `predecessors`: If `predecessors`, a list whose ith element is a list of vectors, the jth of which contains the intervening vertices on all shortest paths from i to j.

Note

`geodist` implicitly treats graphs as unvalued; as such, reported distances may not be correct if all edge weights are non-identical.

gliop

*Return a Binary Operation on GLI Values Computed on Two Graphs*

Description

`gliop` is a wrapper which allows for an arbitrary binary operation on GLIs to be treated as a single call. This is particularly useful for test routines such as `cugtest` and `qaptest`.

Usage

```r
gliop(dat, GFUN, OP=-",
g1=1,
g2=2,
...)```

gliop

Arguments

dat a collection of graphs.
GFUN a function taking single graphs as input.
OP the operator to use on the output of GFUN.
g1 the index of the first input graph.
g2 the index of the second input graph.
... Additional arguments to GFUN

Details

gliop operates by evaluating GFUN on the graphs indexed by g1 and g2 and returning the result of OP as applied to the GFUN output.

Value

OP(GFUN(dat[g1, , ,],...), GFUN(dat[g2, , ,],...))

Note

If the output of GFUN is not sufficiently well-behaved, undefined behavior may occur. Common sense is advised.

gplot

Two-Dimensional Visualization of Graphs

Description

gplot produces a two-dimensional plot of graph g in collection dat. A variety of options are available to control vertex placement, display details, color, etc.

Usage

gplot(dat, g = 1, gmode = "digraph", diag = FALSE, label = NULL, coord = NULL, jitter = TRUE, thresh = 0, usearrows = TRUE, mode = "fruchtermanreingold", displayisolates = TRUE, interactive = FALSE, interact.bycomp = FALSE, label.pad = 0.5, displaylabels = !is.null(label), boxed.labels = TRUE, label.pos = 0, label.bg = "white", vertex.sides = NULL, vertex.rot = 0, arrowhead.cex = 1, label.cex = 1, loop.cex = 1, vertex.cex = 1, edge.col = 1, label.col = 1, vertex.col = NULL, label.border = 1, vertex.border = 1, edge.lty = 1, label.lty = NULL, vertex.lty = 1, edge.lwd = 0, label.lwd = par("lwd"), edge.len = 0.5, edge.curve = 0.1, edge.steps = 50, loop.steps = 20, object.scale = 0.01, uselen = FALSE, usecurve = FALSE, suppress.axes = TRUE, vertices.last = TRUE, new = TRUE, layout.par = NULL, ...)

Arguments

dat a graph or set thereof. This data may be valued.

g integer indicating the index of the graph which is to be plotted. By default, g=1.

gmode String indicating the type of graph being evaluated. "digraph" indicates that edges should be interpreted as directed; "graph" indicates that edges are undirected; "twomode" indicates that data should be interpreted as two-mode (i.e., rows and columns are distinct vertex sets). gmode is set to "digraph" by default.

diag boolean indicating whether or not the diagonal should be treated as valid data. Set this true if and only if the data can contain loops. diag is FALSE by default.

label a vector of vertex labels, if desired; defaults to the vertex index number.

coord user-specified vertex coordinates, in an NCOL(dat)x2 matrix. Where this is specified, it will override the mode setting.

jitter boolean; should the output be jittered?

thresh real number indicating the lower threshold for tie values. Only ties of value >thresh are displayed. By default, thresh=0.

usearrows boolean; should arrows (rather than line segments) be used to indicate edges?

mode the vertex placement algorithm; this must correspond to a gplot.layout function.
<table>

<tr>
<td><code>vertex.cex</code></td>
<td>expansion factor for vertices; may be given as a vector, if vertices are to be of different sizes.</td>
</tr>
<tr>
<td><code>edge.col</code></td>
<td>color for edges; may be given as a vector or adjacency matrix, if edges are to be of different colors.</td>
</tr>
<tr>
<td><code>label.col</code></td>
<td>color for vertex labels; may be given as a vector, if labels are to be of different colors.</td>
</tr>
<tr>
<td><code>vertex.col</code></td>
<td>color for vertices; may be given as a vector, if vertices are to be of different colors. By default, red is used (or red and blue, for two-mode data).</td>
</tr>
<tr>
<td><code>label.border</code></td>
<td>label border colors (if <code>boxed.labels==TRUE</code>); may be given as a vector, if label boxes are to have different colors.</td>
</tr>
<tr>
<td><code>vertex.border</code></td>
<td>border color for vertices; may be given as a vector, if vertex borders are to be of different colors.</td>
</tr>
</tbody>
</table>
edge.lty  line type for edge borders; may be given as a vector or adjacency matrix, if edge borders are to have different line types.

label.lty  line type for label boxes (if boxed.labels==TRUE); may be given as a vector, if label boxes are to have different line types.

vertex.lty  line type for vertex borders; may be given as a vector or adjacency matrix, if vertex borders are to have different line types.

edge.lwd  line width scale for edges; if set greater than 0, edge widths are scaled by edge.lwd*dat. May be given as a vector or adjacency matrix, if edges are to have different line widths.

label.lwd  line width for label boxes (if boxed.labels==TRUE); may be given as a vector, if label boxes are to have different line widths.

edge.len  if use.len==TRUE, curved edge lengths are scaled by edge.len.

edge.curve  if use.curve==TRUE, the extent of edge curvature is controlled by edge.curv. May be given as a fixed value, vector, or adjacency matrix, if edges are to have different levels of curvature.

edge.steps  for curved edges (excluding loops), the number of line segments to use for the curve approximation.

loop.steps  for loops, the number of line segments to use for the curve approximation.

object.scale  base length for plotting objects, as a fraction of the linear scale of the plotting region. Defaults to 0.01.

uselen  boolean; should we use edge.len to rescale edge lengths?

usecurve  boolean; should we use edge.curve?

suppress.axes  boolean; suppress plotting of axes?

vertices.last  boolean; plot vertices after plotting edges?

new  boolean; create a new plot? If new==FALSE, vertices and edges will be added to the existing plot.

layout.par  parameters to the gplot.layout function specified in mode.

...  additional arguments to plot.

details

gplot is the standard network visualization tool within the sna library. By means of clever selection of display parameters, a fair amount of display flexibility can be obtained. Graph layout – if not specified directly using coord – is determined via one of the various available algorithms. These should be specified via the mode argument; see gplot.layout for a full list. User-supplied layout functions are also possible – see the aforementioned man page for details.

Note that where gmode="twomode", the supplied two-mode network is converted to bipartite form prior to computing coordinates (if not in that form already). vertex.col or other settings may be used to differentiate row and column vertices – by default, row vertices are drawn as red octagons, and column vertices are rendered as blue squares. If interactive==TRUE, then the user may modify the initial graph layout by selecting an individual vertex and then clicking on the location to which this vertex is to be moved; this process may be repeated until the layout is satisfactory. If interact.bycomp==TRUE as well, the vertex and all other vertices in the same component as that vertex are moved together.
gplot.arrow

Add Arrows or Segments to a Plot

Description

gplot.arrow draws a segment or arrow between two pairs of points; unlike arrows or segments, the new plot element is drawn as a polygon.

Usage

gplot.arrow(x0, y0, x1, y1, length = 0.1, angle = 20, width = 0.01, col = 1, border = 1, lty = 1, offset.head = 0, offset.tail = 0, arrowhead = TRUE, curve = 0, edge.steps = 50, ...)

Arguments

- **x0**: A vector of x coordinates for points of origin
- **y0**: A vector of y coordinates for points of origin
- **x1**: A vector of x coordinates for destination points
- **y1**: A vector of y coordinates for destination points
- **length**: Arrowhead length, in current plotting units
- **angle**: Angle of arrow in degrees
- **width**: Width of arrow in current plotting units
- **col**: Color of line
- **border**: Color of border
- **lty**: Line type
- **offset.head**: Offset for arrowhead
- **offset.tail**: Offset for arrowtail
- **arrowhead**: If TRUE, draw an arrowhead; FALSE if not
- **curve**: Curve of arrow
- **edge.steps**: Number of steps for drawing the arrow
- **displaylabels**: If TRUE, display labels on the arrow
- **label.bg**: Background color for labels

Examples

```r
# A colorful demonstration...
gplot.rgraph(5, diag=TRUE), diag=TRUE, vertex.cex=1:5, vertex.sides=3:8,
vertex.col=1:5, vertex.border=2:6, vertex.rot=(0:4)*72,
displaylabels=TRUE, label.bg="gray90")
```
angle    Arrowhead angle (in degrees)
width    Width for arrow body, in current plotting units (can be a vector)
col      Arrow body color (can be a vector)
border   Arrow border color (can be a vector)
lty      Arrow border line type (can be a vector)
offset.head  Offset for destination point (can be a vector)
offset.tail  Offset for origin point (can be a vector)
arrowhead Boolean; should arrowheads be used? (Can be a vector)
curve    Degree of edge curvature (if any), in current plotting units (can be a vector)
edge.steps For curved edges, the number of steps to use in approximating the curve (can be a vector)
...      Additional arguments to polygon

details

\texttt{gplot.arrow} provides a useful extension of \texttt{segments} and \texttt{arrows} when fine control is needed over the resulting display. (The results also look better.) Note that edge curvature is quadratic, with \texttt{curve} providing the maximum horizontal deviation of the edge (left-handed). Head/tail offsets are used to adjust the end/start points of an edge, relative to the baseline coordinates; these are useful for functions like \texttt{gplot}, which need to draw edges incident to vertices of varying radii.

Value

None.

\end{verbatim}
gplot.layout  

**Vertex Layout Functions for gplot**

**Description**

Various functions which generate vertex layouts for the `gplot` visualization routine.

**Usage**

```r

gplot.layout.adj(d, layout.par)  
gplot.layout.circle(d, layout.par)  
gplot.layout.circrand(d, layout.par)  
gplot.layout.eigen(d, layout.par)  
gplot.layout.fruchtermanreingold(d, layout.par)  
gplot.layout.geodist(d, layout.par)  
gplot.layout.hall(d, layout.par)  
gplot.layout.kamadakawai(d, layout.par)  
gplot.layout.mds(d, layout.par)  
gplot.layout.princoord(d, layout.par)  
gplot.layout.random(d, layout.par)  
gplot.layout.rmds(d, layout.par)  
gplot.layout.segeo(d, layout.par)  
gplot.layout.seham(d, layout.par)  
gplot.layout.spring(d, layout.par)  
gplot.layout.springrepulse(d, layout.par)  
gplot.layout.target(d, layout.par)
```

**Arguments**

- `d` an adjacency matrix, as passed by `gplot`.
- `layout.par` a list of parameters.

**Details**

Vertex layouts for network visualization pose a difficult problem – there is no single, “good” layout algorithm, and many different approaches may be valuable under different circumstances. With this in mind, `gplot` allows for the use of arbitrary vertex layout algorithms via the `gplot.layout.*` family of routines. When called, `gplot` searches for a `gplot.layout` function whose third name matches its mode argument (see `gplot` help for more information); this function is then used to generate the layout for the resulting plot. In addition to the routines documented here, users may add their own layout functions as needed. The requirements for a `gplot.layout` function are as follows:

1. the first argument, `d`, must be the (dichotomous) graph adjacency matrix;
2. the second argument, `layout.par`, must be a list of parameters (or `NULL`, if no parameters are specified); and
3. the return value must be a real matrix of dimension `c(2, NROW(d))`, whose rows contain the vertex coordinates.

Other than this, anything goes. (In particular, note that `layout.par` could be used to pass additional matrices, if needed.)

The `graph.layout` functions currently supplied by default are as follows:
circle  This function places vertices uniformly in a circle; it takes no arguments.

eigen  This function places vertices based on the eigenstructure of the adjacency matrix. It takes
the following arguments:

  layout.par$var  This argument controls the matrix to be used for the eigenanalysis. "symupper",
"symlower", "symstrong", "symweak" invoke symmetrize on d with the respective symmetrizing rule. "user"
indicates a user-supplied matrix (see below), while "raw" indicates that d should be used as-is. (Defaults to "raw".)

  layout.par$evsel  If "first", the first two eigenvectors are used; if "size", the two eigenvectors
whose eigenvalues have the largest magnitude are used instead. Note that only
the real portion of the associated eigenvectors is used. (Defaults to "first".)

  layout.par$mat  If layout.par$var=="user", this matrix is used for the eigenanalysis.
  (No default.)

fruchtermanreingold  This function generates a layout using a variant of Fruchterman and Rein-
gold’s force-directed placement algorithm. It takes the following arguments:

  layout.par$niter  This argument controls the number of iterations to be employed. (Defaults
to 500.)

  layout.par$max.delta  Sets the maximum change in position for any given iteration. (Def-
  auIts to NROW(d).)

  layout.par$area  Sets the "area" parameter for the F-R algorithm. (Defaults to NROW(d)^2.)

  layout.par$cool.exp  Sets the cooling exponent for the annealer. (Defaults to 3.)

  layout.par$repulse.rad  Determines the radius at which vertex-vertex repulsion cancels out
attraction of adjacent vertices. (Defaults to area*NROW(d).)

  layout.par$seed.coord  A two-column matrix of initial vertex coordinates. (Defaults to a
random circular layout.)

hall  This function places vertices based on the last two eigenvectors of the Laplacian of the input
matrix (Hall’s algorithm). It takes no arguments.

kamadakawai  This function generates a vertex layout using a version of the Kamada-Kawai force-
directed placement algorithm. It takes the following arguments:

  layout.par$niter  This argument controls the number of iterations to be employed. (Defaults
to 1000.)

  layout.par$sigma  Sets the base standard deviation of position change proposals. (Defaults
to NROW(d)/4.)

  layout.par$initemp  Sets the initial "temperature" for the annealing algorithm. (Defaults to
  10.)

  layout.par$cool.exp  Sets the cooling exponent for the annealer. (Defaults to 0.99.)

  layout.par$kkconst  Sets the Kamada-Kawai vertex attraction constant. (Defaults to NROW(d)^2.)

  layout.par$elen  Provides the matrix of interpoint distances to be approximated. (Defaults to
the geodesic distances of d after symmetrizing, capped at sqrt(NROW(d)).)

  layout.par$seed.coord  A two-column matrix of initial vertex coordinates. (Defaults to a
gaussian layout.)

mds  This function places vertices based on a metric multidimensional scaling of a specified distance
matrix. It takes the following arguments:

  layout.par$var  This argument controls the raw variable matrix to be used for the subse-
quent distance calculation and scaling. "rowcol", "row", and "col" indicate that the
rows and columns (concatenated), rows, or columns (respectively) of d should be used.
"rcsum" and "rcdiff" result in the sum or difference of d and its transpose being
employed. "invadj" indicates that max(d)-d should be used, while "geodist" uses
geodist to generate a matrix of geodesic distances from d. Alternately, an arbitrary
matrix can be provided using "user". (Defaults to "rowcol".)
**layout.par$dist** The distance function to be calculated on the rows of the variable matrix. This must be one of the method parameters to `list(dist)("euclidean", "maximum", "manhattan", or "canberra"), or else "none". In the latter case, no distance function is calculated, and the matrix in question must be square (with dimension `dim(d)` for the routine to work properly. (Defaults to "euclidean").

**layout.par$exp** The power to which distances should be raised prior to scaling. (Defaults to 2.)

**layout.par$vm** If `layout.par$var="user"`, this matrix is used for the distance calculation. (No default.)

Note: the following layout functions are based on `mds`:

- **adj** scaling of the raw adjacency matrix, treated as similarities (using "invadj").
- **geodist** scaling of the matrix of geodesic distances.
- **rmds** euclidean scaling of the rows of `d`.
- **segeo** scaling of the squared euclidean distances between row-wise geodesic distances (i.e., approximate structural equivalence).
- **seham** scaling of the Hamming distance between rows/columns of `d` (i.e., another approximate structural equivalence scaling).

**princoord** This function places vertices based on the eigenstructure of a given correlation/covariance matrix. It takes the following arguments:

- **layout.par$var** The matrix of variables to be used for the correlation/covariance calculation. "rowcol", "col", and "row" indicate that the rows/cols, columns, or rows (respectively) of `d` should be employed. "rcsum", "rcdiff" result in the sum or difference of `d` and `t(d)` being used. "user" allows for an arbitrary variable matrix to be supplied. (Defaults to "rowcol".)

- **layout.par$cor** Should the correlation matrix (rather than the covariance matrix) be used? (Defaults to TRUE.)

- **layout.par$vm** If `layout.par$var="user"`, this matrix is used for the correlation/covariance calculation. (No default.)

**random** This function places vertices randomly. It takes the following argument:

- **layout.par$dist** The distribution to be used for vertex placement. Currently, the options are "unif" (for uniform distribution on the square), "uniang" (for a "gaussian donut" configuration), and "normal" (for a straight Gaussian distribution). (Defaults to "unif".)

Note: **circrand**, which is a frontend to the "uniang" option, is based on this function.

**spring** This function places vertices using a spring embedder. It takes the following arguments:

- **layout.par$mass** The vertex mass (in "quasi-kilograms"). (Defaults to 0.1.)

- **layout.par$equil** The equilibrium spring extension (in "quasi-meters"). (Defaults to 1.)

- **layout.par$k** The spring coefficient (in "quasi-Newton quasi-meter"). (Defaults to 0.001.)

- **layout.par$repeqdis** The point at which repulsion (if employed) balances out the spring extension force (in "quasi-meters"). (Defaults to 0.1.)

- **layout.par$kfr** The base coefficient of kinetic friction (in "quasi-Newton quasi-kilograms"). (Defaults to 0.01.)

- **layout.par$repulse** Should repulsion be used? (Defaults to FALSE.)

Note: **springrepulse** is a frontend to `spring`, with repulsion turned on.

**target** This function produces a "target diagram" or "bullseye" layout, using a Brandes et al.'s force-directed placement algorithm. (See also `gplot.target`.) It takes the following arguments:

- **layout.par$niter** This argument controls the number of iterations to be employed. (Defaults to 1000.)
gplot.loop

**layout.par$radii** This argument should be a vector of length \( \text{NROW}(d) \) containing vertex radii. Ideally, these should lie in the [0,1] interval (and odd behavior may otherwise result). (Defaults to the affine-transformed Freeman degree centrality scores of \( d \).)

**layout.par$minlen** Sets the minimum edge length, below which edge lengths are to be adjusted upwards. (Defaults to 0.05.)

**layout.par$area** Sets the initial "temperature" for the annealing algorithm. (Defaults to 10.)

**layout.par$cool.exp** Sets the cooling exponent for the annealer. (Defaults to 0.99.)

**layout.par$maxdelta** Sets the maximum angular distance for vertex moves. (Defaults to \( \pi \).)

**layout.par$periph.outside** Boolean; should "peripheral" vertices (in the Brandes et al. sense) be placed together outside the main target area? (Defaults to FALSE.)

**layout.par$periph.outside.offset** Radius at which to place "peripheral" vertices if \( \text{periph.outside}==\text{TRUE} \). (Defaults to 1.2.)

**layout.par$disconst** Multiplier for the Kamada-Kawai-style distance potential. (Defaults to 1.)

**layout.par$crossconst** Multiplier for the edge crossing potential. (Defaults to 1.)

**layout.par$repconst** Multiplier for the vertex-edge repulsion potential. (Defaults to 1.)

**layout.par$minpdis** Sets the "minimum distance" parameter for vertex repulsion. (Defaults to 0.05.)

**Value**

A matrix whose rows contain the x,y coordinates of the vertices of \( d \).

**gplot.loop**  
*Add Loops to a Plot*

**Description**

gplot.loop draws a "loop" at a specified location; this is used to designate self-ties in gplot.
gplot.loop

Usage

gplot.loop(x0, y0, length = 0.1, angle = 10, width = 0.01, col = 1, border = 1, lty = 1, offset = 0, edge.steps = 10, radius = 1, arrowhead = TRUE, xctr=0, yctr=0, ...)

Arguments

x0  a vector of x coordinates for points of origin.
y0  a vector of y coordinates for points of origin.
length  arrowhead length, in current plotting units.
angle  arrowhead angle (in degrees).
width  width for loop body, in current plotting units (can be a vector).
col  loop body color (can be a vector).
border  loop border color (can be a vector).
lty  loop border line type (can be a vector).
offset  offset for origin point (can be a vector).
edge.steps  number of steps to use in approximating curves.
radius  loop radius (can be a vector).
arrowshead  boolean; should arrowheads be used? (Can be a vector.)
xctr  x coordinate for the central location away from which loops should be oriented.
yctr  y coordinate for the central location away from which loops should be oriented.
...  additional arguments to polygon.

Details

gplot.loop is the companion to gplot.arrow; like the latter, plot elements produced by gplot.loop are drawn using polygon, and as such are scaled based on the current plotting device. By default, loops are drawn so as to encompass a circular region of radius radius, whose center is offset units from x0,y0 and at maximum distance from xctr,yctr. This is useful for functions like gplot, which need to draw loops incident to vertices of varying radii.

Value

None.

          offset=sqrt(2)/4,angle=20,radius=0.5,edge.steps=50,arrowhead=TRUE)
polygon(c(0.25,-0.25,-0.25,0.25,NA,0.25,-0.25,-0.25,0.25),
        c(1.25,1.25,0.75,0.75,NA,-1.25,-1.25,-0.75,-0.75),col=c(2,3))

gplot.target

Display a Graph in Target Diagram Form

Description

Displays an input graph (and associated vector) as a "target diagram," with vertices restricted to lie at fixed radii from the origin. Such displays are useful ways of representing vertex characteristics and/or local structural properties for graphs of small to medium size.

Usage

gplot.target(dat, x, circ.rad = (1:10)/10, circ.col = "blue",
circ.lwd = 1, circ.lty = 3, circ.lab = TRUE, circ.lab.cex = 0.75,
circ.lab.theta = pi, circ.lab.col = 1, circ.lab.digits = 1,
circ.lab.offset = 0.025, periph.outside = FALSE,
periph.outside.offset = 1.2, ...)

Arguments

dat an input graph.
x a vector of vertex properties to be plotted (must match the dimensions of dat).
circ.rad radii at which to draw reference circles.
circ.col reference circle color.
circ.lwd reference circle line width.
circ.lty reference circle line type.
circ.lab boolean; should circle labels be displayed?
circ.lab.cex expansion factor for circle labels.
circ.lab.theta angle at which to draw circle labels.
circ.lab.col color for circle labels.
circ.lab.digits digits to display for circle labels.
circ.lab.offset offset for circle labels.
periph.outside boolean; should "peripheral" vertices be drawn together beyond the normal vertex radius?
periph.outside.offset radius at which "peripheral" vertices should be drawn if periph.outside==TRUE.
... additional arguments to gplot.
gplot.target is a front-end to gplot which implements the target diagram layout of Brandes et al. (2003). This layout seeks to optimize various aesthetic criteria, given the constraint that all vertices lie at fixed radii from the origin (set by x). One important feature of this algorithm is that vertices which belong to mutual dyads (described by Brandes et al. as “core” vertices) are treated differently from vertices which do not (“peripheral” vertices). Layout is optimized for core vertices prior to placing peripheral vertices; thus, the result may be misleading if mutuality is not a salient characteristic of the data.

The layout for gplot.target is handled by gplot.layout.target; additional parameters are specified on the associated manual page. Standard arguments may be passed to gplot, as well.

Value

A two-column matrix of vertex positions (generated by gplot.layout.target)

Author(s)

Carter T. Butts (butts@uci.edu)

References

---

**gplot.vertex**  
*Add Vertices to a Plot*

**Description**

* gplot.vertex adds one or more vertices (drawn using polygon) to a plot.

**Usage**

```r
?gplot.vertex(x, y, radius = 1, sides = 4, border = 1, col = 2, lty = NULL, rot = 0, ...)
```
Arguments

- `x`: a vector of x coordinates.
- `y`: a vector of y coordinates.
- `radius`: a vector of vertex radii.
- `sides`: a vector containing the number of sides to draw for each vertex.
- `border`: a vector of vertex border colors.
- `col`: a vector of vertex interior colors.
- `lty`: a vector of vertex border line types.
- `rot`: a vector of vertex rotation angles (in degrees).
- `...`: Additional arguments to `polygon`

Details

`gplot.vertex` draws regular polygons of specified radius and number of sides, at the given coordinates. This is useful for routines such as `gplot`, which use such shapes to depict vertices.

Value

None

**gplot3d**

*Three-Dimensional Visualization of Graphs*

Description

`gplot3d` produces a three-dimensional plot of graph `g` in set `dat`. A variety of options are available to control vertex placement, display details, color, etc.
**Usage**

gplot3d(dat, g = 1, gmode = "digraph", diag = FALSE, label = NULL, coord = NULL, jitter = TRUE, thresh = 0, mode = "fruchtermanreingold", displayisolates = TRUE, displaylabels = !missing(label), xlab = NULL, ylab = NULL, zlab = NULL, vertex.radius = NULL, absolute.radius = FALSE, label.col = "gray50", edge.col = "black", vertex.col = NULL, edge.alpha = 1, vertex.alpha = 1, edge.lwd = NULL, suppress.axes = TRUE, new = TRUE, bg.col = "white", layout.par = NULL)

**Arguments**

dat  
a graph or set thereof. This data may be valued.
g  
integer indicating the index of the graph (from dat) which is to be displayed.
gmode  
string indicating the type of graph being evaluated. "digraph" indicates that edges should be interpreted as directed; "graph" indicates that edges are undirected; "twomode" indicates that data should be interpreted as two-mode (i.e., rows and columns are distinct vertex sets).
diag  
boolean indicating whether or not the diagonal should be treated as valid data. Set this true if and only if the data can contain loops.
label  
a vector of vertex labels; setting this to a zero-length string (e.g., "") omits
coord  
user-specified vertex coordinates, in an NCOL(dat)x3 matrix. Where this is specified, it will override the mode setting.
jitter  
boolean; should vertex positions be jittered?
thresh  
real number indicating the lower threshold for tie values. Only ties of value >thresh are displayed.
mode  
the vertex placement algorithm; this must correspond to a gplot3d.layout function.
displayisolates  
boolean; should isolates be displayed?
displaylabels  
boolean; should vertex labels be displayed?
xlab  
X axis label.
mlab  
Y axis label.
zlab  
Z axis label.
vertex.radius  
vertex radius, relative to the baseline (which is set based on layout features); may be given as a vector, if radii vary across vertices.
absolute.radius  
vertex radius, specified in absolute terms; this may be given as a vector.
label.col  
color for vertex labels; may be given as a vector, if labels are to be of different colors.
edge.col  
color for edges; may be given as a vector or adjacency matrix, if edges are to be of different colors.
vertex.col  
color for vertices; may be given as a vector, if vertices are to be of different colors. By default, red is used (or red and blue, if gmode=="twomode").
edge.alpha  
alpha (transparency) values for edges; may be given as a vector or adjacency matrix, if edge transparency is to vary.
vertex.alpha alpha (transparency) values for vertices; may be given as a vector, if vertex transparency is to vary.

draw.circle boolean; draw circles at vertex locations?
edge.lwd line width scale for edges; if set greater than 0, edge widths are rescaled by edge.lwd+dat. May be given as a vector or adjacency matrix, if edges are to have different line widths.

suppress.axes boolean; suppress plotting of axes?

new boolean; create a new plot? If new==FALSE, the RGL device will not be cleared prior to adding vertices and edges.

bg.col background color for display.

layout.par list of parameters to the gplot.layout function specified in mode.

Details
gplot3d is the three-dimensional companion to gplot. As with the latter, clever manipulation of parameters can allow for a great deal of flexibility in the resulting display. (Displays produced by gplot3d are also interactive, to the extent supported by rgl.) If vertex positions are not specified directly using coord, vertex layout is determined via one of the various available algorithms. These should be specified via the mode argument; see gplot3d.layout for a full list. User-supplied layout functions are also possible - see the aforementioned man page for details.

Note that where gmode="twomode", the supplied two-mode graph is converted to bipartite form prior to computing coordinates (assuming it is not in this form already). It may be desirable to use parameters such as vertex.col to differentiate row and column vertices; by default, row vertices are colored red, and column vertices blue.

Value

A three-column matrix containing vertex coordinates

Requires

rgl

### gplot3d.arrow

Add Arrows a Three-Dimensional Plot

**Description**

`gplot3d.arrow` draws an arrow between two pairs of points.

**Usage**

```
gplot3d.arrow(a, b, radius, color = "white", alpha = 1)
```

**Arguments**

- `a`: a vector or three-column matrix containing origin X,Y,Z coordinates.
- `b`: a vector or three-column matrix containing origin X,Y,Z coordinates.
- `radius`: the arrow radius, in current plotting units. May be a vector, if multiple arrows are to be drawn.
- `color`: the arrow color. May be a vector, if multiple arrows are being drawn.
- `alpha`: alpha (transparency) value(s) for arrows. (May be a vector.)

**Details**

`gplot3d.arrow` draws one or more three-dimensional "arrows" from the points given in `a` to those given in `b`. Note that the "arrows" are really cones, narrowing in the direction of the destination point.

**Value**

None.

gplot3d.layout  Vertex Layout Functions for gplot3d

Description
Various functions which generate vertex layouts for the gplot3d visualization routine.

Usage

\[
gplot3d.layout.adj(d, layout.par)
gplot3d.layout.eigen(d, layout.par)
gplot3d.layout.fruchtermanreingold(d, layout.par)
gplot3d.layout.geodist(d, layout.par)
gplot3d.layout.hall(d, layout.par)
gplot3d.layout.kamadakawai(d, layout.par)
gplot3d.layout.mds(d, layout.par)
gplot3d.layout.princoord(d, layout.par)
gplot3d.layout.random(d, layout.par)
gplot3d.layout.rmds(d, layout.par)
gplot3d.layout.segeo(d, layout.par)
gplot3d.layout.seham(d, layout.par)
\]

Arguments

- \(d\) an adjacency matrix, as passed by gplot3d.
- layout.par a list of parameters.

Details

Like gplot, gplot3d allows for the use of arbitrary vertex layout algorithms via the gplot3d.layout.* family of routines. When called, gplot3d searches for a gplot3d.layout function whose third name matches its mode argument (see gplot3d help for more information); this function is then used to generate the layout for the resulting plot. In addition to the routines documented here, users may add their own layout functions as needed. The requirements for a gplot3d.layout function are as follows:

1. the first argument, \(d\), must be the (dichotomous) graph adjacency matrix;
2. the second argument, layout.par, must be a list of parameters (or NULL, if no parameters are specified); and
3. the return value must be a real matrix of dimension \(c(3,NROW(d))\), whose rows contain the vertex coordinates.

Other than this, anything goes. (In particular, note that layout.par could be used to pass additional matrices, if needed.)

The gplot3d.layout functions currently supplied by default are as follows:

**eigen** This function places vertices based on the eigenstructure of the adjacency matrix. It takes the following arguments:

- \(layout.par$var\) This argument controls the matrix to be used for the eigenanalysis. "symupper", "symlower", "symstrong", "symweak" invoke symmetrize on \(d\) with the respective symmetrizing rule. "user" indicates a user-supplied matrix (see below), while "raw" indicates that \(d\) should be used as-is. (Defaults to "raw".)
layout.par$evsel If "first", the first three eigenvectors are used; if "size", the three eigenvectors whose eigenvalues have the largest magnitude are used instead. Note that only the real portion of the associated eigenvectors is used. (Defaults to "first").

layout.par$mat If layout.par$var=="user", this matrix is used for the eigenanalysis. (No default.)

fruchtermanreingold This function generates a layout using a variant of Fruchterman and Reingold's force-directed placement algorithm. It takes the following arguments:

layout.par$niter This argument controls the number of iterations to be employed. (Defaults to 300.)

layout.par$max.delta Sets the maximum change in position for any given iteration. (Defaults to NROW(d).)

layout.par$volume Sets the "volume" parameter for the F-R algorithm. (Defaults to NROW(d) ^ 3.)

layout.par$cool.exp Sets the cooling exponent for the annealer. (Defaults to 3.)

layout.par$repulse.rad Determines the radius at which vertex-vertex repulsion cancels out attraction of adjacent vertices. (Defaults to volume*NROW(d).)

layout.par$seed.coord A three-column matrix of initial vertex coordinates. (Defaults to a random spherical layout.)

hall This function places vertices based on the last three eigenvectors of the Laplacian of the input matrix (Hall's algorithm). It takes no arguments.

kamadakawai This function generates a vertex layout using a version of the Kamada-Kawai force-directed placement algorithm. It takes the following arguments:

layout.par$niter This argument controls the number of iterations to be employed. (Defaults to 1000.)

layout.par$sigma Sets the base standard deviation of position change proposals. (Defaults to NROW(d) / 4.)

layout.par$init.temp Sets the initial "temperature" for the annealing algorithm. (Defaults to 10.)

layout.par$cool.exp Sets the cooling exponent for the annealer. (Defaults to 0.99.)

layout.par$kconst Sets the Kamada-Kawai vertex attraction constant. (Defaults to NROW(d) ^ 3.)

layout.par$elen Provides the matrix of interpoint distances to be approximated. (Defaults to the geodesic distances of d after symmetrizing, capped at sqrt(NROW(d)).)

layout.par$seed.coord A three-column matrix of initial vertex coordinates. (Defaults to a gaussian layout.)

mds This function places vertices based on a metric multidimensional scaling of a specified distance matrix. It takes the following arguments:

layout.par$var This argument controls the raw variable matrix to be used for the subsequent distance calculation and scaling. "rowcol", "row", and "col" indicate that the rows and columns (concatenated), rows, or columns (respectively) of d should be used. "rcsum" and "rcdiff" result in the sum or difference of d and its transpose being employed. "invadj" indicates that max(d) - d should be used, while "geodist" uses geodist to generate a matrix of geodesic distances from d. Alternately, an arbitrary matrix can be provided using "user". (Defaults to "rowcol").

layout.par$dist The distance function to be calculated on the rows of the variable matrix. This must be one of the method parameters to \{\text{dist}\} ("euclidean", "maximum", "manhattan", or "canberra"), or else "none". In the latter case, no distance function is calculated, and the matrix in question must be square (with dimension dim(d)) for the routine to work properly. (Defaults to "euclidean").

layout.par$exp The power to which distances should be raised prior to scaling. (Defaults to 2.)
layout.par$vm  If layout.par$var=="user", this matrix is used for the distance calculation. (No default.)

Note: the following layout functions are based on mds:
adj  scaling of the raw adjacency matrix, treated as similarities (using "invadj").
geodist  scaling of the matrix of geodesic distances.
rmds  euclidean scaling of the rows of d.
segeo  scaling of the squared euclidean distances between row-wise geodesic distances (i.e., approximate structural equivalence).
seham  scaling of the Hamming distance between rows/columns of d (i.e., another approximate structural equivalence scaling).

princoord  This function places vertices based on the eigenstructure of a given correlation/covariance matrix. It takes the following arguments:

layout.par$var  The matrix of variables to be used for the correlation/covariance calculation. "rowcol", "col", and "row" indicate that the rows/cols, columns, or rows (respectively) of d should be employed. "rcsum" "rcdiff" result in the sum or difference of d and t(d) being used. "user" allows for an arbitrary variable matrix to be supplied. (Defaults to "rowcol").

layout.par$cor  Should the correlation matrix (rather than the covariance matrix) be used? (Defaults to TRUE.)

layout.par$vm  If layout.par$var=="user", this matrix is used for the correlation/covariance calculation. (No default.)

random  This function places vertices randomly. It takes the following argument:

layout.par$dist  The distribution to be used for vertex placement. Currently, the options are "unif" (for uniform distribution on the unit cube), "uniang" (for a “gaussian sphere” configuration), and "normal" (for a straight Gaussian distribution). (Defaults to "unif".)

Value
A matrix whose rows contain the x,y,z coordinates of the vertices of d.

### gplot3d.loop

Add Loops to a Three-Dimensional Plot

#### Description

gplot3d.loop draws a "loop" at a specified location; this is used to designate self-ties in gplot3d.

#### Usage

gplot3d.loop(a, radius, color = "white", alpha = 1)

#### Arguments

- **a**: a vector or three-column matrix containing origin X,Y,Z coordinates.
- **radius**: the loop radius, in current plotting units. May be a vector, if multiple loops are to be drawn.
- **color**: the loop color. May be a vector, if multiple loops are being drawn.
- **alpha**: alpha (transparency) value(s) for loops. (May be a vector.)

#### Details

gplot3d.loop is the companion to gplot3d.arrow. The "loops" produced by this routine currently look less like loops than like "hats" – they are noticeable as spike-like structures which protrude from vertices. Eventually, something more attractive will be produced by this routine.

#### Value

None.

### graphcent

Compute the (Harary) Graph Centrality Scores of Network Positions

#### Description

graphcent takes one or more graphs (dat) and returns the Harary graph centralities of positions (selected by nodes) within the graphs indicated by g. Depending on the specified mode, graph centrality on directed or undirected geodesics will be returned; this function is compatible with centralization, and will return the theoretical maximum absolute deviation (from maximum) conditional on size (which is used by centralization to normalize the observed centralization score).
graphcent

Usage

graphcent(dat, g=1, nodes=NULL, gmode="digraph", diag=FALSE,
          tmaxdev=FALSE, cmode="directed", geodist.precomp=NULL,
          rescale=FALSE, ignore.eval)

Arguments

dat one or more input graphs.
g integer indicating the index of the graph for which centralities are to be calculated (or a vector thereof). By default, g==1.
nodes list indicating which nodes are to be included in the calculation. By default, all nodes are included.
gmode string indicating the type of graph being evaluated. "digraph" indicates that edges should be interpreted as directed; "graph" indicates that edges are undirected. gmode is set to "digraph" by default.
diag boolean indicating whether or not the diagonal should be treated as valid data. Set this true if and only if the data can contain loops. diag is FALSE by default.
tmaxdev boolean indicating whether or not the theoretical maximum absolute deviation from the maximum nodal centrality should be returned. By default, tmaxdev==FALSE.
cmode string indicating the type of graph centrality being computed (directed or undirected geodesics).
geodist.precomp a geodist object precomputed for the graph to be analyzed (optional)
rescale if true, centrality scores are rescaled such that they sum to 1.
ignore.eval logical; should edge values be ignored when calculating geodesics?

Details

The Harary graph centrality of a vertex v is equal to \( \frac{1}{\max_u d(v,u)} \), where \( d(v,u) \) is the geodesic distance from v to u. Vertices with low graph centrality scores are likely to be near the “edge” of a graph, while those with high scores are likely to be near the “middle.” Compare this with closeness, which is based on the reciprocal of the sum of distances to all other vertices (rather than simply the maximum).

Value

A vector, matrix, or list containing the centrality scores (depending on the number and size of the input graphs).

Note

Judicious use of geodist.precomp can save a great deal of time when computing multiple path-based indices on the same network.

graphcent(g)        #Compute centrality scores
```

---

**grecip**

*Compute the Reciprocity of an Input Graph or Graph Stack*

**Description**

`grecip` calculates the dyadic reciprocity of the elements of `dat` selected by `g`.

**Usage**

```
grecip(dat, g = NULL, measure = c("dyadic", "dyadicnonnull", "edgewise", "edgewise.lrr"))
```

**Arguments**

- `dat`: one or more input graphs.
- `g`: a vector indicating which graphs to evaluate (optional).
- `measure`: one of "dyadic" (default), "dyadicnonnull", "edgewise", or "edgewise.lrr".

**Details**

The dyadic reciprocity of a graph is the proportion of dyads which are symmetric; this is computed and returned by `grecip` for the graphs indicated. (dyadicnonnull returns the ratio of mutuals to non-null dyads.) Note that the dyadic reciprocity is distinct from the *edgewise or tie reciprocity*, which is the proportion of *edges* which are reciprocated. This latter form may be obtained by setting `measure="edgewise"`. Setting `measure="edgewise.lrr"` returns the log of the ratio of the edgewise reciprocity to the density; this is measure (called $r_4$ by Butts (2008)) can be interpreted as the relative log-odds of an edge given a reciprocation, versus the baseline probability of an edge.

**Value**

The graph reciprocity value(s)

**Author(s)**

gscor

Find the Structural Correlations Between Two or More Graphs

gscor finds the product-moment structural correlation between the adjacency matrices of graphs indicated by g1 and g2 in stack dat (or possibly dat2) given exchangeability list exchange.list. Missing values are permitted.

Usage

gscor(dat, dat2=NULL, g1=NULL, g2=NULL, diag=FALSE, mode="digraph", method="anneal", reps=1000, prob.init=0.9, prob.decay=0.85, freeze.time=25, full.neighborhood=TRUE, exchange.list=0)

Arguments

dat a stack of input graphs.
dat2 optionally, a second graph stack.
g1 the indices of dat reflecting the first set of graphs to be compared; by default, all members of dat are included.
g2 the indices or dat (or dat2, if applicable) reflecting the second set of graphs to be compared; by default, all members of dat are included.
diag boolean indicating whether or not the diagonal should be treated as valid data. Set this true if and only if the data can contain loops. diag is FALSE by default.
mode string indicating the type of graph being evaluated. "digraph" indicates that edges should be interpreted as directed; "graph" indicates that edges are undirected. mode is set to "digraph" by default.
method method to be used to search the space of accessible permutations; must be one of "none", "exhaustive", "anneal", "hillclimb", or "mc".
reps number of iterations for Monte Carlo method.
prob.init initial acceptance probability for the annealing routine.
prob.decay cooling multiplier for the annealing routine.
freeze.time freeze time for the annealing routine.
full.neighborhood should the annealer evaluate the full neighborhood of pair exchanges at each iteration?
exchange.list information on which vertices are exchangeable (see below); this must be a single number, a vector of length n, or a nx2 matrix.

Examples

#Calculate the dyadic reciprocity scores for some random graphs
grecip(rgraph(10,5))

mutuality, symmetrize
Details

The structural correlation coefficient between two graphs \( G \) and \( H \) is defined as

\[
\text{scor}(G, H | L_G, L_H) = \max_{\ell_G, \ell_H} \text{cor}(\ell(G), \ell(H))
\]

where \( L_G \) is the set of accessible permutations/labelings of \( G \), \( \ell(G) \) is a permutation/relabeling of \( G \), and \( \ell(G) \in L_G \). The set of accessible permutations on a given graph is determined by the theoretical exchangeability of its vertices; in a nutshell, two vertices are considered to be theoretically exchangeable for a given problem if all predictions under the conditioning theory are invariant to a relabeling of the vertices in question (see Butts and Carley (2001) for a more formal exposition). Where no vertices are exchangeable, the structural correlation becomes the simple graph correlation. Where all vertices are exchangeable, the structural correlation reflects the correlation between unlabeled graphs; other cases correspond to correlation under partial labeling.

The accessible permutation set is determined by the \textit{exchange.list} argument, which is dealt with in the following manner. First, \textit{exchange.list} is expanded to fill an \( nx2 \) matrix. If \textit{exchange.list} is a single number, this is trivially accomplished by replication; if \textit{exchange.list} is a vector of length \( n \), the matrix is formed by cbinding two copies together. If \textit{exchange.list} is already an \( nx2 \) matrix, it is left as-is. Once the \( nx2 \) exchangeability matrix has been formed, it is interpreted as follows: columns refer to graphs 1 and 2, respectively; rows refer to their corresponding vertices in the original adjacency matrices; and vertices are taken to be theoretically exchangeable iff their corresponding exchangeability matrix values are identical. To obtain an unlabeled graph correlation (the default), then, one could simply let \textit{exchange.list} equal any single number. To obtain the standard graph correlation, one would use the vector \( 1:n \).

Because the set of accessible permutations is, in general, very large \( (o(n!)) \), searching the set for the maximum correlation is a non-trivial affair. Currently supported methods for estimating the structural correlation are hill climbing, simulated annealing, blind monte carlo search, or exhaustive search (it is also possible to turn off searching entirely). Exhaustive search is not recommended for graphs larger than size 8 or so, and even this may take days; still, this is a valid alternative for small graphs. Blind monte carlo search and hill climbing tend to be suboptimal for this problem and are not, in general recommended, but they are available if desired. The preferred (and default) option for permutation search is simulated annealing, which seems to work well on this problem (though some tinkering with the annealing parameters may be needed in order to get optimal performance). See the help for \texttt{lab.optimize} for more information regarding these options.

Structural correlation matrices are p.s.d., and are p.d. so long as no graph within the set is a linear combination of any other under any accessible permutation. Their eigendecompositions are meaningful and they may be used in linear subspace analyses, so long as the researcher is careful to interpret the results in terms of the appropriate set of accessible labelings. Classical null hypothesis tests should not be employed with structural correlations, and QAP tests are almost never appropriate (save in the uniquely labeled case). See \texttt{cugtest} for a more reasonable alternative.

Value

An estimate of the structural correlation matrix

Warning

The search process can be very slow, particularly for large graphs. In particular, the exhaustive method is order factorial, and will take approximately forever for unlabeled graphs of size greater than about 7-9.
Note
Consult Butts and Carley (2001) for advice and examples on theoretical exchangeability.

**gscov**

Find the Structural Covariance(s) Between Two or More Graphs

Description

*gscov* finds the structural covariance between the adjacency matrices of graphs indicated by *g1* and *g2* in stack *dat* (or possibly *dat2*) given exchangeability list *exchange.list*. Missing values are permitted.

Usage

```
gscov(dat, dat2=NULL, g1=NULL, g2=NULL, diag=FALSE, mode="digraph", method="anneal", reps=1000, prob.init=0.9, prob.decay=0.85, freeze.time=25, full.neighborhood=TRUE, exchange.list=0)
```
Arguments

- **dat**: one or more input graphs.
- **dat2**: optionally, a second graph stack.
- **g1**: the indices of **dat** reflecting the first set of graphs to be compared; by default, all members of **dat** are included.
- **g2**: the indices or **dat** (or **dat2**, if applicable) reflecting the second set of graphs to be compared; by default, all members of **dat** are included.
- **diag**: boolean indicating whether or not the diagonal should be treated as valid data. Set this true if and only if the data can contain loops. **diag** is **FALSE** by default.
- **mode**: string indicating the type of graph being evaluated. "digraph" indicates that edges should be interpreted as directed; "graph" indicates that edges are undirected. **mode** is set to "digraph" by default.
- **method**: method to be used to search the space of accessible permutations; must be one of "none", "exhaustive", "anneal", "hillclimb", or "mc".
- **reps**: number of iterations for Monte Carlo method.
- **prob.init**: initial acceptance probability for the annealing routine.
- **prob.decay**: cooling multiplier for the annealing routine.
- **freeze.time**: freeze time for the annealing routine.
- **full.neighborhood**: should the annealer evaluate the full neighborhood of pair exchanges at each iteration?
- **exchange.list**: information on which vertices are exchangeable (see below); this must be a single number, a vector of length n, or a nx2 matrix.

Details

The structural covariance between two graphs G and H is defined as

\[
    scov(G, H | L_G, L_H) = \max_{L_G, L_H} \text{cov}(\ell(G), \ell(H))
\]

where \(L_G\) is the set of accessible permutations/labelings of G, \(\ell(G)\) is a permutation/labeling of G, and \(\ell(G) \in L_G\). The set of accessible permutations on a given graph is determined by the theoretical exchangeability of its vertices; in a nutshell, two vertices are considered to be theoretically exchangeable for a given problem if all predictions under the conditioning theory are invariant to a relabeling of the vertices in question (see Butts and Carley (2001) for a more formal exposition). Where no vertices are exchangeable, the structural covariance becomes the simple graph covariance. Where all vertices are exchangeable, the structural covariance reflects the covariance between unlabeled graphs; other cases correspond to covariance under partial labeling.

The accessible permutation set is determined by the **exchange.list** argument, which is dealt with in the following manner. First, **exchange.list** is expanded to fill an nx2 matrix. If **exchange.list** is a single number, this is trivially accomplished by replication; if **exchange.list** is a vector of length n, the matrix is formed by cbinding two copies together. If **exchange.list** is already an nx2 matrix, it is left as-is. Once the nx2 exchangeability matrix has been formed, it is interpreted as follows: columns refer to graphs 1 and 2, respectively; rows refer to their corresponding vertices in the original adjacency matrices; and vertices are taken to be theoretically exchangeable iff their corresponding exchangeability matrix values are identical. To obtain an unlabeled graph covariance (the default), then, one could simply let **exchange.list** equal any single number. To obtain the standard graph covariance, one would use the vector 1:n.
Because the set of accessible permutations is, in general, very large ($o(n!)$), searching the set for the maximum covariance is a non-trivial affair. Currently supported methods for estimating the structural covariance are hill climbing, simulated annealing, blind monte carlo search, or exhaustive search (it is also possible to turn off searching entirely). Exhaustive search is not recommended for graphs larger than size 8 or so, and even this may take days; still, this is a valid alternative for small graphs. Blind monte carlo search and hill climbing tend to be suboptimal for this problem and are not, in general recommended, but they are available if desired. The preferred (and default) option for permutation search is simulated annealing, which seems to work well on this problem (though some tinkering with the annealing parameters may be needed in order to get optimal performance). See the help for \texttt{lab.optimize} for more information regarding these options.

Structural covariance matrices are p.s.d., and are p.d. so long as no graph within the set is a linear combination of any other under any accessible permutation. Their eigendecompositions are meaningful and they may be used in linear subspace analyses, so long as the researcher is careful to interpret the results in terms of the appropriate set of accessible labelings. Classical null hypothesis tests should not be employed with structural covariances, and QAP tests are almost never appropriate (save in the uniquely labeled case). See \texttt{cugtest} for a more reasonable alternative.

## gt

### Transpose an Input Graph

#### Description

`gt` returns the graph transpose of its input. For an adjacency matrix, this is the same as using `t`; however, this function is also applicable to sna edgelists (which cannot be transposed in the usual fashion). Code written using `gt` instead of `t` is thus guaranteed to be safe for either form of input.

#### Usage

```r
gt(x, return.as.edgelist = FALSE)
```

#### Arguments

- `x` one or more graphs.
- `return.as.edgelist` logical; should the result be returned in sna edgelist form?

#### Details

The transpose of a (di)graph, $G = (V,E)$, is the graph $G' = (V,E')$ where $E' = \{(j,i) : (i,j) \in E\}$. This is simply the graph formed by reversing the sense of the edges.

#### Value

The transposed graph(s).

#### Author(s)

Carter T. Butts (buttsc@uci.edu)

#### See Also

`symmetrize`, `t`
Examples

```r
#Create a graph....
g<-rgraph(5)
g
g#Transpose it
gt(g)
gt(g)==t(g) #For adjacency matrices, same as t(g)

#Now, see both versions in edgelist form
as.edgelist.sna(g)
gt(g,return.as.edgelist=TRUE)
```

---

gtrans

Compute the Transitivity of an Input Graph or Graph Stack

Description

gtrans returns the transitivity of the elements of dat selected by g, using the definition of measure. Triads involving missing values are omitted from the analysis.

Usage

gtrans(dat, g=NULL, diag=FALSE, mode="digraph", measure = c("weak", "strong", "weakcensus", "strongcensus"), use.adjacency = TRUE)

Arguments

dat a collection of input graphs.
g a vector indicating the graphs which are to be analyzed; by default, all graphs are analyzed.
diag a boolean indicating whether or not diagonal entries (loops) are to be taken as valid data.
mode "digraph" if directed triads are sought, or else "graph".
measure one of "weak" (default), "strong", "weakcensus", or "strongcensus".
use.adjacency logical; should adjacency matrices (versus sparse graph methods) be used in the transitivity computation?

Details

Transitivity is a triadic, algebraic structural constraint. In its weak form, the transitive constraint corresponds to $a \rightarrow b \rightarrow c \Rightarrow a \rightarrow c$. In the corresponding strong form, the constraint is $a \rightarrow b \rightarrow c \Leftrightarrow a \rightarrow c$. (Note that the weak form is that most commonly employed.) Where measure="weak", the fraction of potentially intransitive triads obeying the weak condition is returned. With the measure="weakcensus" setting, by contrast, the total number of transitive triads is computed. The strong versions of the measures are similar to the above, save in that the set of all triads is considered (since all are "at risk" for intransitivity).

Note that the default method used here employs matrix multiplication to calculate transitivity scores. For very large, sparse graphs, the sparse graph method (use.adjacency=FALSE) may be preferred. The latter provides much better scaling, but is significantly slower for networks of typical size due to the overhead involved (and R's highly optimized matrix operations).
**gvectorize**

**Value**
A vector of transitivity scores

**Author(s)**
Carter T. Butts (buttsc@uci.edu)

**References**

**See Also**
triad.classify, cugtest

**Examples**
```r
# Draw some random graphs
g <- rgraph(5, 10)

# Find transitivity scores
gtrans(g)
```

---

**gvectorize**

*Vectorization of Adjacency Matrices*

**Description**
`gvectorize` takes an input graph set and converts it into a corresponding number of vectors by row concatenation.

**Usage**
```
gvectorize(mats, mode="digraph", diag=FALSE, censor.as.na=TRUE)
```

**Arguments**
- **mats**: one or more input graphs.
- **mode**: “digraph” if data is taken to be directed, else “graph”.
- **diag**: boolean indicating whether diagonal entries (loops) are taken to contain meaningful data.
- **censor.as.na**: if TRUE, code unused parts of the adjacency matrix as NAs prior to vectorizing; otherwise, unused parts are simply removed.
Details

The output of gvectorize is a matrix in which each column corresponds to an input graph, and each row corresponds to an edge. The columns of the output matrix are formed by simple row-concatenation of the original adjacency matrices, possibly after removing cells which are not meaningful (if censor.as.na==FALSE). This is useful when preprocessing edge sets for use with glm or the like.

Value

An nxk matrix, where n is the number of arcs and k is the number of graphs; if censor.as.na==FALSE, n will be reflect the relevant number of uncensored arcs.

Author(s)

Carter T. Butts (buttsc@uci.edu)

Examples

#Draw two random graphs
g<-rgraph(10,2)

#Examine the vectorized form of the adjacency structure
gvectorize(g)

hdist

Find the Hamming Distances Between Two or More Graphs

Description

hdist returns the Hamming distance between the labeled graphs g1 and g2 in set dat for dichotomous data, or else the absolute (manhattan) distance. If normalize is true, this distance is divided by its dichotomous theoretical maximum (conditional on |V(G)|).

Usage

hdist(dat, dat2=NULL, g1=NULL, g2=NULL, normalize=FALSE, diag=FALSE, mode="digraph")

Arguments

dat a stack of input graphs.
dat2 a second graph stack (optional).
g1 a vector indicating which graphs to compare (by default, all elements of dat).
g2 a vector indicating against which the graphs of g1 should be compared (by default, all graphs).
normalize divide by the number of available dyads?
diag boolean indicating whether or not the diagonal should be treated as valid data. Set this true if and only if the data can contain loops. diag is FALSE by default.
mode string indicating the type of graph being evaluated. "digraph" indicates that edges should be interpreted as directed; "graph" indicates that edges are undirected. mode is set to "digraph" by default.
Details

The Hamming distance between two labeled graphs $G_1$ and $G_2$ is equal to $|\{e : (e \in E(G_1), e \not\in E(G_2)) \land (e \not\in E(G_1), e \in E(G_2))\}|$. In more prosaic terms, this may be thought of as the number of addition/deletion operations required to turn the edge set of $G_1$ into that of $G_2$. The Hamming distance is a highly general measure of structural similarity, and forms a metric on the space of graphs (simple or directed). Users should be reminded, however, that the Hamming distance is extremely sensitive to nodal labeling, and should not be employed directly when nodes are interchangeable. The structural distance (Butts and Carley (2001)), implemented in `structdist`, provides a natural generalization of the Hamming distance to the more general case of unlabeled graphs.

Null hypothesis testing for Hamming distances is available via `cugtest`, and `qaptest`; graphs which minimize the Hamming distances to all members of a graph set can be found by `centralgraph`. For an alternative means of comparing the similarity of graphs, consider `gcor`.

Value

A matrix of Hamming distances

Note

For non-dichotomous data, the distance which is returned is simply the sum of the absolute edge-wise differences.

```
hierarchy  

Compute Graph Hierarchy Scores

Description

hierarchy takes a graph set (dat) and returns reciprocity or Krackhardt hierarchy scores for the graphs selected by g.

Usage

hierarchy(dat, g=NULL, measure=c("reciprocity", "krackhardt"))

Arguments

dat a stack of input graphs.
g  index values for the graphs to be utilized; by default, all graphs are selected.
measure one of "reciprocity" or "krackhardt".

Details

Hierarchy measures quantify the extent of asymmetry in a structure; the greater the extent of asymmetry, the more hierarchical the structure is said to be. (This should not be confused with how centralized the structure is, i.e., the extent to which centralities of vertex positions are highly concentrated.) hierarchy provides two measures (selected by the measure argument) as follows:

1. reciprocity: This setting returns one minus the dyadic reciprocity for each input graph (see grecip)
2. krackhardt: This setting returns the Krackhardt hierarchy score for each input graph. The Krackhardt hierarchy is defined as the fraction of non-null dyads in the reachability graph which are asymmetric. Thus, when no directed paths are reciprocated (e.g., in an in/outtree), Krackhardt hierarchy is equal to 1; when all such paths are reciprocated, by contrast (e.g., in a cycle or clique), the measure falls to 0.

Hierarchy is one of four measures (connectedness, efficiency, hierarchy, and lubness) suggested by Krackhardt for summarizing hierarchical structures. Each corresponds to one of four axioms which are necessary and sufficient for the structure in question to be an outtree; thus, the measures will be equal to 1 for a given graph iff that graph is an outtree. Deviations from unity can be interpreted in terms of failure to satisfy one or more of the outtree conditions, information which may be useful in classifying its structural properties.

Note that hierarchy is inherently density-constrained: as densities climb above 0.5, the proportion of mutual dyads must (by the pigeonhole principle) increase rapidly, thereby reducing possibilities for asymmetry. Thus, the interpretation of hierarchy scores should take density into account, particularly if density is artifactual (e.g., due to a particular dichotomization procedure).

Value

A vector of hierarchy scores
The four Krackhardt indices are, in general, nondegenerate for a relatively narrow band of size/density combinations (efficiency being the sole exception). This is primarily due to their dependence on the reachability graph, which tends to become complete rapidly as size/density increase. See Krackhardt (1994) for a useful simulation study.

hierarchy(rgraph(10,5,tprob=c(0.1,0.25,0.5,0.75,0.9)),
    measure="krackhardt")

infocent

Find Information Centrality Scores of Network Positions

Description

infocent takes one or more graphs (dat) and returns the information centralities of positions (selected by nodes) within the graphs indicated by g. This function is compatible with centralization, and will return the theoretical maximum absolute deviation (from maximum) conditional on size (which is used by centralization to normalize the observed centralization score).

Usage

infocent(dat, g=1, nodes=NULL, gmode="digraph", diag=FALSE,
    cmode="weak", tmaxdev=FALSE, rescale=FALSE, tol=1e-20)
Arguments

- **dat**: one or more input graphs.
- **g**: integer indicating the index of the graph for which centralities are to be calculated (or a vector thereof). By default, `g==1`.
- **nodes**: list indicating which nodes are to be included in the calculation. By default, all nodes are included.
- **gmode**: string indicating the type of graph being evaluated. "digraph" indicates that edges should be interpreted as directed; "graph" indicates that edges are undirected. This is currently ignored.
- **diag**: boolean indicating whether or not the diagonal should be treated as valid data. Set this true if and only if the data can contain loops. `diag` is `FALSE` by default.
- **cmode**: the rule to be used by `symmetrize` when symmetrizing dichotomous data; must be one of "weak" (for an OR rule), "strong" for an AND rule), "upper" (for a max rule), or "lower" (for a min rule). Set to "weak" by default, this parameter obviously has no effect on symmetric data.
- **tmaxdev**: boolean indicating whether or not the theoretical maximum absolute deviation from the maximum nodal centrality should be returned. By default, `tmaxdev==FALSE`.
- **rescale**: if true, centrality scores are rescaled such that they sum to 1.
- **tol**: tolerance for near-singularities during matrix inversion (see `solve`).

Details

Actor information centrality is a hybrid measure which relates to both path-length indices (e.g., closeness, graph centrality) and to walk-based eigenmeasures (e.g., eigenvector centrality, Bonacich power). In particular, the information centrality of a given actor can be understood to be the harmonic average of the “bandwidth” for all paths originating with said individual (where the bandwidth is taken to be inversely related to path length). Formally, the index is constructed as follows. First, we take $G$ to be an undirected (but possibly valued) graph – symmetrizing if necessary – with (possibly valued) adjacency matrix $A$. From this, we remove all isolates (whose information centralities are zero in any event) and proceed to create the weighted connection matrix $C = B^{-1}$

where $B$ is a pseudo-adjacency matrix formed by replacing the diagonal of $1 - A$ with one plus each actor’s degree. Given the above, let $T$ be the trace of $C$ with sum $S_T$, and let $S_R$ be an arbitrary row sum (all rows of $C$ have the same sum). The information centrality scores are then equal to

$$C_I = \frac{1}{T + \frac{S_T - 2S_R}{|\{e\}|}}$$

(recalling that the scores for any omitted vertices are 0).

In general, actors with higher information centrality are predicted to have greater control over the flow of information within a network; highly information-central individuals tend to have a large number of short paths to many others within the social structure. Because the raw centrality values can be difficult to interpret directly, rescaled values are sometimes preferred (see the `rescale` option). Though the use of path weights suggest information centrality as a possible replacement for closeness, the problem of inverting the $B$ matrix poses problems of its own; as with all such measures, caution is advised on disconnected or degenerate structures.
Value

A vector, matrix, or list containing the centrality scores (depending on the number and size of the input graphs).

Note

The theoretical maximum deviation used here is not obtained with the star network; rather, the maximum occurs for an empty graph with one complete dyad, which is the model used here.

---

interval.graph

Convert Spell Data to Interval Graphs

Description

Constructs one or more interval graphs (and exchangeability vectors) from a set of spells.

Usage

interval.graph(slist, type="simple", diag=FALSE)

Arguments

slist

A spell list. This must consist of an nxmx3 array, with n being the number of actors, m being the maximum number of spells (one per row) and with the three columns of the last dimension containing a (categorical) spell type code, the time of spell onset (any units), and the time of spell termination (same units), respectively.

type

One of “simple”, “overlap”, “fracxy”, “fracyx”, or “jntfrac”.

diag

Include the dyadic entries?
Details

Given some ordering dimension T (usually time), a “spell” is defined as the interval between a specified onset and a specified termination (with onset preceding the termination). An interval graph, then, on spell set V, is \( G = \{ V, E \} \), where \( \{ i, j \} \in E \) iff there exists some point \( t \in T \) such that \( t \in i \) and \( t \in j \). In more prosaic terms, an interval graph on a given spell set has each spell as a vertex, with vertices adjacent iff they overlap. Such structures are useful for quantifying life history data (where spells might represent marriages, periods of child custody/co-residence, periods of employment, etc.), organizational history data (where spells might reflect periods of strategic alliances, participation in a particular product market, etc.), task scheduling (with spells representing the dedication of a particular resource to a given task), etc. By giving complex historical data a graphic representation, it is possible to easily perform a range of analyses which would otherwise be difficult and/or impossible (see Butts and Pixley (2004) for examples).

In addition to the simple interval graph (described above), \texttt{interval.graph} can also generate valued interval graphs using a number of different edge definitions. This is controlled by the \texttt{type} argument, with edge values as follows:

1. simple: dichotomous coding based on simple overlap (i.e., \((x,y)=1\) iff \(x\) overlaps \(y\))
2. overlap: edge value equals the total magnitude of the overlap between spells
3. fracxy: the \((x,y)\) edge value equals the fraction of the duration of \(y\) which is covered by \(x\)
4. fracyx: the \((x,y)\) edge value equals the fraction of the duration of \(x\) which is covered by \(y\)
5. jntfrac: edge value equals the total magnitude of the overlap between spells divided by the mean of the spells’ lengths

Note that “simple,” “overlap,” and “jntfrac” are symmetric relations, while “fracxy” and “fracyx” are directed. As always, the specific edge type used should reflect the application to which the interval graph is being put.

Value

A data frame containing:

\begin{itemize}
\item \texttt{graph} A graph stack containing the interval graphs
\item \texttt{exchange.list} Matrix containing the vector of spell types associated with each interval graph
\end{itemize}

is.connected

Is a Given Graph Connected?

Description

Returns TRUE iff the specified graphs are connected.

Usage

is.connected(g, connected = "strong", comp.dist.precomp = NULL)

Arguments

g one or more input graphs.
connected definition of connectedness to use; must be one of "strong", "weak", "unilateral", or "recursive".
comp.dist.precomp a component.dist object precomputed for the graph to be analyzed (optional).

Details

is.connected determines whether the elements of g are connected under the definition specified in connected. (See component.dist for details.) Since is.connected is really just a wrapper for component.dist, an object created with the latter can be supplied (via comp.dist.precomp) to speed computation.

Value

TRUE iff g is connected, otherwise FALSE

Author(s)

Carter T. Butts (buttsc@uci.edu)

References

See Also

component.dist.components

Examples

#Generate two graphs:
g1<-rgraph(10,tp=0.1)
g2<-rgraph(10)

#Check for connectedness
is.connected(g1)  #Probably not
is.connected(g2)  #Probably so
is.isolate  Is Ego an Isolate?

Description

Returns TRUE iff ego is an isolate in graph g of dat.

Usage

is.isolate(dat, ego, g=1, diag=FALSE)

Arguments

dat  one or more input graphs.

ego  index of the vertex (or a vector of vertices) to check.

g  which graph should be examined?

diag  boolean indicating whether adjacency matrix diagonals (i.e., loops) contain meaning-

Details

In the valued case, any non-zero edge value is taken as sufficient to establish a tie.

Value

A boolean value (or vector thereof) indicating isolate status

   g[4,]<-0
```

#Check for isolates

```r
   is.isolate(g,2)  #2 is almost surely not an isolate
   is.isolate(g,4)  #4 is, by construction
```
isolates

List the Isolates in a Graph or Graph Stack

Description

Returns a list of the isolates in the graph or graph set given by dat.

Usage

isolates(dat, diag=FALSE)

Arguments

dat one or more input graphs.
diag boolean indicating whether adjacency matrix diagonals (i.e., loops) contain meaningful data.

Value

A vector containing the isolates, or a list of vectors if more than one graph was specified

Author(s)

Carter T. Butts (buttscc@uci.edu)

References

g<-rgraph(20)
g[,4]<-0 #Create an isolate
g[4,]<-0

#List the isolates
isolates(g)
`kcores` calculates the k-core structure of the input network, using the centrality measure indicated in `cmode`.

**Usage**

```r
kcores(dat, mode = "digraph", diag = FALSE, cmode = "freeman", ignore.eval = FALSE)
```

**Arguments**

- `dat`: one or more (possibly valued) graphs.
- `mode`: "digraph" for directed data, otherwise "graph".
- `diag`: logical; should self-ties be included in the degree calculations?
- `cmode`: the degree centrality mode to use when constructing the cores.
- `ignore.eval`: logical; should edge values be ignored when computing degree?

**Details**

Let $G = (V, E)$ be a graph, and let $f(v, S, G)$ for $v \in V, S \subseteq V$ be a real-valued vertex property function (in the language of Batagelj and Zaversnik). Then some set $H \subseteq V$ is a generalized k-core for $f$ if $H$ is a maximal set such that $f(v, H, G) \geq k$ for all $v \in H$. Typically, $f$ is chosen to be a degree measure with respect to $S$ (e.g., the number of ties to vertices in $S$). In this case, the resulting k-cores have the intuitive property of being maximal sets such that every set member is tied (in the appropriate manner) to at least k others within the set.

Degree-based k-cores are a simple tool for identifying well-connected structures within large graphs. Let the core number of vertex $v$ be the value of the highest-value core containing $v$. Then, intuitively, vertices with high core numbers belong to relatively well-connected sets (in the sense of sets with high minimum internal degree). It is important to note that, while a given k-core need not be connected, it is composed of subsets which are themselves well-connected; thus, the k-cores can be thought of as unions of relatively cohesive subgroups. As k-cores are nested, it is also natural to think of each k-core as representing a “slice” through a hypothetical “cohesion surface” on $G$. (Indeed, k-cores are often visualized in exactly this manner.)

The `kcores` function produces degree-based k-cores, for various degree measures (with or without edge values). The return value is the vector of core numbers for $V$, based on the selected degree measure. Missing (i.e., NA) edge are removed for purposes of the degree calculation.

**Value**

A vector containing the maximum core membership for each vertex.

**kpath.census**

*Compute Path or Cycle Census Information*

**Description**

`kpath.census` and `kcycle.census` compute $k$-path or $k$-cycle census statistics (respectively) on one or more input graphs. In addition to aggregate counts of paths or cycles, results may be disaggregated by vertex and co-membership information may be computed.

**Usage**

```r
kcycle.census(dat, maxlen = 3, mode = "digraph",
              tabulate.by.vertex = TRUE, cycle.comembership = c("none", "sum",
                             "bylength"))

kpath.census(dat, maxlen = 3, mode = "digraph",
             tabulate.by.vertex = TRUE, path.comembership = c("none", "sum",
                               "bylength"), dyadic.tabulation = c("none", "sum", "bylength"))
```

**Arguments**

- `cycle.comembership` the type of cycle co-membership information to be tabulated, if any. "sum" returns a vertex by vertex matrix of cycle co-membership counts; these are disaggregated by cycle length if "bylength" is used. If "none" is given, no co-membership information is computed.
- `dat` one or more input graphs.
The maximum path/cycle length to evaluate.

"digraph" for directed graphs, or "graph" for undirected graphs.

Should path or cycle incidence counts be tabulated by vertex?

As per cycle.comembership, for paths rather than cycles.

The type of dyadic path count information to be tabulated, if any. "sum" returns a vertex by vertex matrix of source/destination path counts, while "bylength" disaggregates these counts by path length. Selecting "none" disables this computation.

There are several equivalent characterizations of paths and cycles, of which the following is one example. For an arbitrary graph $G$, a path is a sequence of distinct vertices $v_1, v_2, \ldots, v_n$ and included edges such that $v_i$ is adjacent to $v_{i+1}$ for all $i \in 1, 2, \ldots, n - 1$ via the pair's included edge. (Contrast this with a walk, in which edges and/or vertices may be repeated.) A cycle is the union of a path and an edge making $v_n$ adjacent to $v_i$. $k$-paths and $k$-cycles are respective paths and cycles having $k$ edges (in the former case) or $k$ vertices (in the latter). The above definitions may be applied in both directed and undirected contexts, by substituting the appropriate notion of adjacency. (Note that authors do not always employ the same terminology for these concepts, especially in older texts – it is wise to verify the definitions being used in any particular context.)

A subgraph census statistic is a function which, for any given graph and subgraph, gives the number of copies of the latter contained in the former. A collection of subgraph census statistics is referred to as a subgraph census; widely used examples include the dyad and triad censuses, implemented in sna by the dyad.census and triad.census functions (respectively). kpath.census and kcycle.census compute a range of census statistics related to $k$-paths and $k$-cycles, including:

- Aggregate counts of paths/cycles by length (i.e., $k$).
- Counts of paths/cycles to which each vertex belongs (when tabulate.byvertex==TRUE).
- Counts of path/cycle co-memberships, potentially disaggregated by length (when the appropriate co-membership argument is set to bylength).
- For path.census, counts of the total number of paths from each vertex to each other vertex, possibly disaggregated by length (if dyadic.tabulation=="bylength").

The length of the maximum-length path/cycle to compute is given by maxlen. These calculations are intrinsically expensive (path/cycle computation is NP complete in the general case), and users should hence be wary when increasing maxlen. On the other hand, it may be possible to enumerate even long paths or cycles on a very sparse graph; scaling is approximately $c^k$, where $k$ is given by maxlen and $c$ is the size of the largest dense cluster.

The paths or cycles computed by this function are directed if mode=="digraph", or undirected if mode=="graph". Failing to set mode correctly may result in problematic behavior.

For kpath.census, a list with the following elements:

- path.count: If tabulate.byvertex==FALSE, a vector of aggregate counts by path length. Otherwise, a matrix whose first column is a vector of aggregate path counts, and whose succeeding columns contain vectors of path counts for each vertex.
path.comemb  If path.comembership!="none", a matrix or array containing co-membership in paths by vertex pairs. If path.comembership=="sum", only a matrix of co-memberships is returned; if bylength is used, however, co-memberships are returned in a maxlen by n by n array whose i,j,kth cell is the number of paths of length i containing j and k.

paths.bydyad  If dyadic.tabulation!="none", a matrix or array containing the number of paths originating at a particular vertex and terminating. If bylength is used, dyadic path counts are supplied via a maxlen by n by n array whose i,j,kth cell is the number of paths of length i starting at j and ending with k. If sum is used instead, only a matrix whose i,j cell contains the total number of paths from i to j is returned.

cycle.count  If tabulate.byvertex==FALSE, a vector of aggregate counts by cycle length. Otherwise, a matrix whose first column is a vector of aggregate cycle counts, and whose succeeding columns contain vectors of cycle counts for each vertex.

cycle.comemb  If cycle.comembership!="none", a matrix or array containing co-membership in cycles by vertex pairs. If cycle.comembership=="sum", only a matrix of co-memberships is returned; if bylength is used, however, co-memberships are returned in a maxlen by n by n array whose i,j,kth cell is the number of cycles of length i containing j and k.

Warning
The computational cost of calculating paths and cycles grows very sharply in both maxlen and network density. Be wary of setting maxlen greater than 5-6, unless you know what you are doing. Otherwise, the expected completion time for your calculation may exceed your life expectancy (and those of subsequent generations).

lab.optimize

Optimize a Bivariate Graph Statistic Across a Set of Accessible Permutations

Description

lab.optimize is the front-end to a series of heuristic optimization routines (see below), all of which seek to maximize/minimize some bivariate graph statistic (e.g., graph correlation) across a set of vertex relabelings.

Usage

lab.optimize(d1, d2, FUN, exchange.list=0, seek="min", opt.method=c("anneal", "exhaustive", "mc", "hillclimb", "gumbel"), ...)
lab.optimize.anneal(d1, d2, FUN, exchange.list=0, seek="min", prob.init=1, prob.decay=0.99, freeze.time=1000, full.neighborhood=TRUE, ...)
lab.optimize.exhaustive(d1, d2, FUN, exchange.list=0, seek="min", ...)
lab.optimize.gumbel(d1, d2, FUN, exchange.list=0, seek="min", draws=500, tol=1e-5, estimator="median", ...)
lab.optimize.hillclimb(d1, d2, FUN, exchange.list=0, seek="min", ...)
lab.optimize.mc(d1, d2, FUN, exchange.list=0, seek="min", draws=1000, ...)

Arguments

d1 a single graph.
d2 another single graph.
FUN a function taking two graphs as its first two arguments, and returning a numeric value.
exchange.list information on which vertices are exchangeable (see below); this must be a single number, a vector of length n, or a nx2 matrix.
seek "min" if the optimizer should seek a minimum, or "max" if a maximum should be sought.
opt.method the particular optimization method to use.
prob.init initial acceptance probability for a downhill move (lab.optimize.anneal only).
prob.decay the decay (cooling) multiplier for the probability of accepting a downhill move (lab.optimize.anneal only).
freeze.time  number of iterations at which the annealer should be frozen (lab.optimize.anneal only).

full.neighborhood  should all moves in the binary-exchange neighborhood be evaluated at each iteration? (lab.optimize.anneal only).

tol  tolerance for estimation of gumbel distribution parameters (lab.optimize.gumbel only).

estimator  Gumbel distribution statistic to use as optimal value prediction; must be one of “mean”, “median”, or “mode” (lab.optimize.gumbel only).

draws  number of draws to take for gumbel and mc methods.

...  additional arguments to FUN.

Details

lab.optimize is the front-end to a family of routines for optimizing a bivariate graph statistic over a set of permissible relabelings (or equivalently, permutations). The accessible permutation set is determined by the exchange.list argument, which is dealt with in the following manner. First, exchange.list is expanded to fill an nx2 matrix. If exchange.list is a single number, this is trivially accomplished by replication; if exchange.list is a vector of length n, the matrix is formed by cbinding two copies together. If exchange.list is already an nx2 matrix, it is left as-is. Once the nx2 exchangeability matrix has been formed, it is interpreted as follows: columns refer to graphs 1 and 2, respectively; rows refer to their corresponding vertices in the original adjacency matrices; and vertices are taken to be theoretically exchangeable iff their corresponding exchangeability matrix values are identical. To obtain an unlabeled graph statistic (the default), then, one could simply let exchange.list equal any single number. To obtain the labeled statistic, one would use the vector 1:n.

Assuming a non-degenerate set of accessible permutations/relabelings, optimization proceeds via the algorithm specified in opt.method. The optimization routines which are currently implemented use a variety of different techniques, each with certain advantages and disadvantages. A brief summary of each is as follows:

1. exhaustive search (“exhaustive”): Under exhaustive search, the entire space of accessible permutations is combed for the global optimum. This guarantees a correct answer, but at a very high price: the set of all permutations grows with the factorial of the number of vertices, and even substantial exchangeability constraints are unlikely to keep the number of permutations from growing out of control. While exhaustive search is possible for small graphs, unlabeled structures of size approximately 10 or greater cannot be treated using this algorithm within a reasonable time frame.

   Approximate complexity: on the order of \( \prod_{i \in L} |V_i|! \), where L is the set of exchangeability classes.

2. hill climbing (“hillclimb”): The hill climbing algorithm employed here searches, at each iteration, the set of all permissible binary exchanges of vertices. If one or more exchanges are found which are superior to the current permutation, the best alternative is taken. If no superior alternative is found, then the algorithm terminates. As one would expect, this algorithm is guaranteed to terminate on a local optimum; unfortunately, however, it is quite prone to becoming “stuck” in suboptimal solutions. In general, hill climbing is not recommended for permutation search, but the method may prove useful in certain circumstances.

   Approximate complexity: on the order of \( |V(G)|^2 \) per iteration, total complexity dependent on the number of iterations.
3. simulated annealing ("anneal"): The (fairly simple) annealing procedure here employed proceeds as follows. At each iteration, the set of all permissible binary exchanges (if \texttt{full.neighborhood==TRUE}) or a random selection from this set is evaluated. If a superior option is identified, the best of these is chosen. If no superior options are found, then the algorithm chooses randomly from the set of alternatives with probability equal to the current temperature, otherwise retaining its prior solution. After each iteration, the current temperature is reduced by a factor equal to \texttt{prob.decay}; the initial temperature is set by \texttt{prob.init}. When a number of iterations equal to \texttt{freeze.time} have been completed, the algorithm "freezes." Once "frozen," the annealer hillclimbs from its present location until no improvement is found, and terminates. At termination, the best permutation identified so far is utilized; this need not be the most recent position (though it sometimes is).

Simulated annealing is sometimes called "noisy hill climbing" because it uses the introduction of random variation to a hill climbing routine to avoid convergence to local optima; it works well on reasonably correlated search spaces with well-defined solution neighborhoods, and is far more robust than hill climbing algorithms. As a general rule, simulated annealing is recommended here for most graphs up to size approximately 50. At this point, computational complexity begins to become a serious barrier, and alternative methods may be more practical.

Approximate complexity: on the order of $|V(G)|^2*\texttt{freeze.time}$ if \texttt{full.neighborhood==TRUE}, otherwise complexity scales approximately linearly with \texttt{freeze.time}. This can be misleading, however, since failing to search the full neighborhood generally requires that \texttt{freeze.time} be greatly increased.

4. blind monte carlo search ("mc"): Blind monte carlo search, as the name implies, consists of randomly drawing a sample of permutations from the accessible permutation set and selecting the best. Although this not such a bad option when A) a large fraction of points are optimal or nearly optimal and B) the search space is largely uncorrelated, these conditions do not seem to characterize most permutation search problems. Blind monte carlo search is not generally recommended, but it is provided as an option should it be desired (e.g., when it is absolutely necessary to control the number of permutations examined).

Approximate complexity: linear in \texttt{draws}.

5. extreme value estimation ("gumbel"): Extreme value estimation attempts to estimate a global optimum via stochastic modeling of the distribution of the graph statistic over the space of accessible permutations. The algorithm currently proceeds as follows. First, a random sample is taken from the accessible permutation set (as with monte carlo search, above). Next, this sample is used to fit an extreme value (gumbel) model; the gumbel distribution is the limiting distribution of the extreme values from samples under a continuous, unbounded distribution, and we use it here as an approximation. Having fit the model, an associated statistic (the mean, median, or mode as determined by \texttt{estimator}) is then used as an estimator of the global optimum.

Obviously, this approach has certain drawbacks. First of all, our use of the gumbel model in particular assumes an unbounded, continuous underlying distribution, which may or may not be approximately true for any given problem. Secondly, the inherent non-robustness of extremal problems makes the fact that our prediction rests on a string of approximations rather worrisome: our idea of the shape of the underlying distribution could be distorted by a bad sample, our parameter estimation could be somewhat off, etc., any of which could have serious consequences for our extremal prediction. Finally, the prediction which is made by the extreme value model is nonconstructive, in the sense that no permutation need have been found by the algorithm which induces the predicted value. On the bright side, this could allow one to estimate the optimum without having to find it directly; on the dark side, this means that the reported optimum could be a numerical chimera.

At this time, extreme value estimation should be considered experimental, and is not recommended for use on substantive problems. \texttt{lab.optimize.gumbel} is not guaranteed to
work properly, or to produce intelligible results; this may eventually change in future revisions, or the routine may be scrapped altogether.

Approximate complexity: linear in draws.

This list of algorithms is itself somewhat unstable: some additional techniques (canonical labeling and genetic algorithms, for instance) may be added, and some existing methods (e.g., extreme value estimation) may be modified or removed. Every attempt will be made to keep the command format as stable as possible for other routines (e.g., gscov, structdist) which depend on lab.optimize to do their heavy-lifting. In general, it is not expected that the end-user will call lab.optimize directly; instead, most end-user interaction with these routines will be via the structural distance/covariance functions which used them.

Value

The estimated global optimum of FUN over the set of relabelings permitted by exchange.list

lnam

Fit a Linear Network Autocorrelation Model

Description

lnam is used to fit linear network autocorrelation models. These include standard OLS as a special case, although lm is to be preferred for such analyses.
Usage

\texttt{lnam(y, x = NULL, W1 = NULL, W2 = NULL, theta.seed = NULL,}
\texttt{null.model = c("mean\_std", "mean", "std", "none"), method = "BFGS",}
\texttt{control = list(), tol=1e-10)}

Arguments

\texttt{y} a vector of responses.
\texttt{x} a vector or matrix of covariates; if the latter, each column should contain a single
covariate.
\texttt{W1} one or more (possibly valued) graphs on the elements of \texttt{y}.
\texttt{W2} one or more (possibly valued) graphs on the elements of \texttt{y}.
\texttt{theta.seed} an optional seed value for the parameter vector estimation process.
\texttt{null.model} the null model to be fit; must be one of "mean\_std", "mean", "std", or
"none".
\texttt{method} method to be used with \texttt{optim}.
\texttt{control} optional control parameters for \texttt{optim}.
\texttt{tol} convergence tolerance for the MLE (expressed as change in deviance).

Details

\texttt{lnam} fits the linear network autocorrelation model given by

\[ y = W_1y + X\beta + e, \quad e = W_2e + \nu \]

where \texttt{y} is a vector of responses, \texttt{X} is a covariate matrix, \texttt{\nu} \sim \texttt{N}(0, \sigma^2),

\[ W_1 = \sum_{i=1}^p \rho_1iW_{1i}, \quad W_2 = \sum_{i=1}^q \rho_2iW_{2i}, \]

and \texttt{W}_{1i}, \texttt{W}_{2i} are (possibly valued) adjacency matrices.

Intuitively, \texttt{\rho_1} is a vector of "AR"-like parameters (parameterizing the autoregression of each \texttt{y} value
on its neighbors in the graphs of \texttt{W}_1) while \texttt{\rho_2} is a vector of "MA"-like parameters (parameterizing
the autocorrelation of each disturbance in \texttt{y} on its neighbors in the graphs of \texttt{W}_2). In general, the
two models are distinct, and either or both effects may be selected by including the appropriate
matrix arguments.

Model parameters are estimated by maximum likelihood, and asymptotic standard errors are pro-
vided as well; all of the above (and more) can be obtained by means of the appropriate \texttt{print} and
\texttt{summary} methods. A plotting method is also provided, which supplies fit basic diagnostics for
the estimated model. For purposes of comparison, fits may be evaluated against one of four null
models:

1. mean\_std: mean and standard deviation estimated (default).
2. mean: mean estimated; standard deviation assumed equal to 1.
3. std: standard deviation estimated; mean assumed equal to 0.
4. none: no parameters estimated; data assumed to be drawn from a standard normal density.

The default setting should be appropriate for the vast majority of cases, although the others may
have use when fitting "pure" autoregressive models (e.g., without covariates). Although a major
use of the \texttt{lnam} is in controlling for network autocorrelation within a regression context, the model
is subtle and has a variety of uses. (See the references below for suggestions.)
Value

An object of class "lnam" containing the following elements:

- **y**: the response vector used.
- **x**: if supplied, the coefficient matrix.
- **W1**: if supplied, the W1 array.
- **W2**: if supplied, the W2 array.
- **model**: a code indicating the model terms fit.
- **infomat**: the estimated Fisher information matrix for the fitted model.
- **acvm**: the estimated asymptotic covariance matrix for the model parameters.
- **null.model**: a string indicating the null model fit.
- **lnlik.null**: the log-likelihood of y under the null model.
- **df.null.resid**: the residual degrees of freedom under the null model.
- **df.null**: the model degrees of freedom under the null model.
- **null.param**: parameter estimates for the null model.
- **lnlik.model**: the log-likelihood of y under the fitted model.
- **df.model**: the model degrees of freedom.
- **df.residual**: the residual degrees of freedom.
- **df.total**: the total degrees of freedom.
- **rho1**: if applicable, the MLE for rho1.
- **rho1.se**: if applicable, the asymptotic standard error for rho1.
- **rho2**: if applicable, the MLE for rho2.
- **rho2.se**: if applicable, the asymptotic standard error for rho2.
- **sigma**: the MLE for sigma.
- **sigma.se**: the standard error for sigma
- **beta**: if applicable, the MLE for beta.
- **beta.se**: if applicable, the asymptotic standard errors for beta.
- **fitted.values**: the fitted mean values.
- **residuals**: the residuals (response minus fitted); note that these correspond to \hat{e} in the model equation, not \hat{\nu}.
- **disturbances**: the estimated disturbances, i.e., \hat{\nu}.
- **call**: the matched call.

Note

Actual optimization is performed by calls to optim. Information on algorithms and control parameters can be found via the appropriate man pages.

## End(Not run)
```

loadcent  

Compute the Load Centrality Scores of Network Positions

Description

loadcent takes one or more graphs (dat) and returns the load centralities of positions (selected by nodes) within the graphs indicated by g. Depending on the specified mode, load on directed or undirected geodesics will be returned; this function is compatible with centralization, and will return the theoretical maximum absolute deviation (from maximum) conditional on size (which is used by centralization to normalize the observed centralization score).

Usage

```r
loadcent(dat, g = 1, nodes = NULL, gmode = "digraph", diag = FALSE, tmaxdev = FALSE, cmode = "directed", geodist.precomp = NULL, rescale = FALSE, ignore.eval = TRUE)
```
Arguments

- **dat**: one or more input graphs.
- **g**: integer indicating the index of the graph for which centralities are to be calculated (or a vector thereof). By default, g=1.
- **nodes**: vector indicating which nodes are to be included in the calculation. By default, all nodes are included.
- **gmode**: string indicating the type of graph being evaluated. `digraph` indicates that edges should be interpreted as directed; `graph` indicates that edges are undirected. `gmode` is set to `digraph` by default.
- **diag**: logical; should self-ties be treated as valid data. Set this true if and only if the data can contain loops. `diag` is `FALSE` by default.
- **tmaxdev**: logical; return the theoretical maximum absolute deviation from the maximum nodal centrality (instead of the observed centrality scores)? By default, `tmaxdev` is `FALSE`.
- **cmode**: string indicating the type of load centrality being computed (directed or undirected).
- **geodist.precomp**: a `geodist` object precomputed for the graph to be analyzed (optional).
- **rescale**: logical; if true, centrality scores are rescaled such that they sum to 1.
- **ignore.eval**: logical; ignore edge values when computing shortest paths?

Details

Goh et al.’s load centrality (as reformulated by Brandes (2008)) is a betweenness-like measure defined through a hypothetical flow process. Specifically, it is assumed that each vertex sends a unit of some commodity to each other vertex to which it is connected (without edge or vertex capacity constraints), with routing based on a priority system: given an input of flow $x$ arriving at vertex $v$ with destination $v'$, $v$ divides $x$ equally among all neighbors of minimum geodesic distance to the target. The total flow passing through a given $v$ via this process is defined as $v$’s load. Load is a potential alternative to betweenness for the analysis of flow structures operating well below their capacity constraints.

Value

A vector of centrality scores.

lower.tri.remove

Remove the Lower Triangles of Adjacency Matrices in a Graph Stack

Description

Returns the input graph set, with the lower triangle entries removed/replaced as indicated.

Usage

lower.tri.remove(dat, remove.val=NA)

Arguments

dat       one or more input graphs.
remove.val the value with which to replace the existing lower triangles.

Details

lower.tri.remove is simply a convenient way to apply \( g[\text{lower.tri}(g)] \leftarrow \text{remove.val} \) to an entire stack of adjacency matrices at once.

Value

The updated graph set.

Examples

#Generate a random graph stack
g<-rgraph(3,5)
#Remove the lower triangles

g<-lower.tri.remove(g)
lubness

Compute Graph LUBness Scores

Description

lubness takes a graph set (dat) and returns the Krackhardt LUBness scores for the graphs selected by g.

Usage

lubness(dat, g=NULL)

Arguments

dat: one or more input graphs.
g: index values for the graphs to be utilized; by default, all graphs are selected.

Details

In the context of a directed graph G, two actors i and j may be said to have an upper bound iff there exists some actor k such that directed ki and kj paths belong to G. An upper bound ℓ is known as a least upper bound for i and j iff it belongs to at least one ki and kj path (respectively) for all i, j upper bounds k; let L(i, j) be an indicator which returns 1 iff such an ℓ exists, otherwise returning 0. Now, let G_1, G_2, ..., G_n represent the weak components of G. For convenience, we denote the cardinalities of these graphs’ vertex sets by |V(G_i)| = N_i, ∀i ∈ 1, ..., n. Given this, the Krackhardt LUBness of G is given by

\[ 1 - \frac{\sum_{i=1}^{n} \sum_{v_j, v_k \in V(G_i)} (1 - L(v_j, v_k))}{\sum_{i=1}^{n} \frac{1}{2}(N_i - 1)(N_i - 2)} \]

Where all vertex pairs possess a least upper bound, Krackhardt’s LUBness is equal to 1; in general, it approaches 0 as this condition is broached. (This convergence is problematic in certain cases due to the requirement that we sum violations across components; where a graph contains no components of size three or greater, Krackhardt’s LUBness is not well-defined. lubness returns a NaN in these cases.)

LUBness is one of four measures (connectedness, efficiency, hierarchy, and lubness) suggested by Krackhardt for summarizing hierarchical structures. Each corresponds to one of four axioms which are necessary and sufficient for the structure in question to be an outtree; thus, the measures will be equal to 1 for a given graph iff that graph is an outtree. Deviations from unity can be interpreted in terms of failure to satisfy one or more of the outtree conditions, information which may be useful in classifying its structural properties.

Value

A vector of LUBness scores

Note

The four Krackhardt indices are, in general, nondegenerate for a relatively narrow band of size/density combinations (efficiency being the sole exception). This is primarily due to their dependence on the reachability graph, which tends to become complete rapidly as size/density increase. See Krackhardt (1994) for a useful simulation study.

Examples

# Get LUBness scores for graphs of varying densities
lubness(rgraph(10,5,tprob=c(0.1,0.25,0.5,0.75,0.9)))

Description

Returns a graph stack in which each adjacency matrix in dat has been normalized to row stochastic, column stochastic, or row-column stochastic form, as specified by mode.

Usage

make.stochastic(dat, mode="rowcol", tol=0.005,
maxiter=prod(dim(dat)) * 100, anneal.decay=0.01, errpow=1)

Arguments

dat a collection of input graphs.
mode one of “row,” “col,” or “rowcol”.
tol tolerance parameter for the row-column normalization algorithm.
maxiter maximum iterations for the row-column normalization algorithm.
anneal.decay probability decay factor for the row-column annealer.
errpow power to which absolute row-column normalization errors should be raised for the annealer (i.e., the penalty function).

Details

Row and column stochastic matrices are those whose rows and columns sum to 1 (respectively). These are quite straightforwardly produced here by dividing each row (or column) by its sum. Row-column stochastic matrices, by contrast, are those in which each row and each column sums to 1. Here, we try to produce row-column stochastic matrices whose values are as close in proportion to the original data as possible by means of an annealing algorithm. This is probably not optimal in the long term, but the results seem to be consistent where row-column stochasticization of the original data is possible (which it is not in all cases).
The stochasticized adjacency matrices

Rows or columns which sum to 0 in the original data will generate undefined results. This can happen if, for instance, your input graphs contain in- or out-isolates.

Carter T. Butts (buttsc@uci.edu)

Examples

#Generate a test matrix
g<-rgraph(15)

#Make it row stochastic
make.stochastic(g,mode="row")

#Make it column stochastic
make.stochastic(g,mode="col")

#(Try to) make it row-column stochastic
make.stochastic(g,mode="rowcol")

maxflow calculates a matrix of maximum pairwise flows within a (possibly valued) input network.

maxflow(dat, src = NULL, sink = NULL, ignore.eval = FALSE)

dat

src

sink

ignore.eval

one or more input graphs.

optionally, a vector of source vertices; by default, all vertices are selected.

optionally, a vector of sink (or target) vertices; by default, all vertices are selected.

logical; ignore edge values (i.e., assume unit capacities) when computing flow?
Details

`maxflow` computes the maximum flow from each source vertex to each sink vertex, assuming infinite vertex capacities and limited edge capacities. If `ignore.eval==FALSE`, supplied edge values are assumed to contain capacity information; otherwise, all non-zero edges are assumed to have unit capacity.

Note that all flows computed here are pairwise – i.e., when computing the flow from \( v \) to \( v' \), we ignore any other flows which could also be taking place within the network. As a result, it should not be assumed that these flows can be realized simultaneously. (For the latter purpose, the values returned by `maxflow` can be treated as upper bounds.)

Value

A matrix of pairwise maximum flows (if multiple sources/sinks selected), or a single maximum flow value (otherwise).

mutuality
```

Find the Mutuality of a Graph

Description

Returns the mutuality scores of the graphs indicated by `g` in `dat`.

Usage

`mutuality(dat, g=NULL)`

Arguments

dat one or more input graphs.

g a vector indicating which elements of `dat` should be analyzed; by default, all graphs are included.
Details

The mutuality of a digraph G is defined as the number of complete dyads (i.e., i<->j) within G. (Compare this to dyadic reciprocity, the fraction of dyads within G which are symmetric.) Mutuality is commonly employed as a measure of reciprocal tendency within the p* literature; although mutuality can be very hard to interpret in practice, it is much better behaved than many alternative measures.

Value

One or more mutuality scores

#Get mutuality and reciprocity scores
mutuality(g)
grecip(g)  #Compare with mutuality

nacf

Sample Network Covariance and Correlation Functions

Description

nacf computes the sample network covariance/correlation function for a specified variable on a given input network. Moran’s I and Geary’s C statistics at multiple orders may be computed as well.

Usage

nacf(net, y, lag.max = NULL, type = c("correlation", "covariance", "moran", "geary"), neighborhood.type = c("in", "out", "total"), partial.neighborhood = TRUE, mode = "digraph", diag = FALSE, thresh = 0, demean = TRUE)
Arguments

- `net`: one or more graphs.
- `y`: a numerical vector, of length equal to the order of `net`.
- `lag.max`: optionally, the maximum geodesic lag at which to compute dependence (defaults to order `net-1`).
- `type`: the type of dependence statistic to be computed.
- `neighborhood.type`: the type of neighborhood to be employed when assessing dependence (as per `neighborhood`).
- `partial.neighborhood`: logical; should partial (rather than cumulative) neighborhoods be employed at higher orders?
- `mode`: "digraph" for directed graphs, or "graph" if `net` is undirected.
- `diag`: logical; does the diagonal of `net` contain valid data?
- `thresh`: threshold at which to dichotomize `net`.
- `demean`: logical; demean `y` prior to analysis?

Details

`nacf` computes dependence statistics for the vector `y` on network `net`, for neighborhoods of various orders. Specifically, let $A_i$ be the $i$th order adjacency matrix of `net`. The sample network autocovariance of `y` on $A_i$ is then given by

$$
s_i = \frac{y^T A_i y}{E},
$$

where $E = \sum_{(j,k)} A_{ijk}$. Similarly, the sample network autocorrelation in the above case is $\rho_i = s_i/\sigma_0$, where $\sigma_0$ is the variance of `y`. Moran’s $I$ and Geary’s $C$ statistics are defined in the usual fashion as

$$
I_i = \frac{N \sum_{j=1}^{N} \sum_{k=1}^{N} (y_j - \bar{y})(y_k - \bar{y})A_{ijk}}{E \sum_{j=1}^{N} y_j^2},
$$

and

$$
C_i = \frac{(N - 1) \sum_{j=1}^{N} \sum_{k=1}^{N} (y_j - y_k)^2 A_{ijk}}{2E \sum_{j=1}^{N} (y - \bar{y})^2}
$$

respectively, where $N$ is the order of $A_i$ and $\bar{y}$ is the mean of `y`.

The adjacency matrix associated with the $i$th order neighborhood is defined as the identity matrix for order 0, and otherwise depends on the type of neighborhood involved. For input graph $G = (V,E)$, let the base relation, $R$, be given by the underlying graph of $G$ (i.e., $G \cup G^T$) if total neighborhoods are sought, the transpose of $G$ if incoming neighborhoods are sought, or $G$ otherwise. The partial neighborhood structure of order $i > 0$ on $R$ is then defined to be the digraph on $V$ whose edge set consists of the ordered pairs $(j,k)$ having geodesic distance $i$ in $R$. The corresponding cumulative neighborhood is formed by the ordered pairs having geodesic distance less than or equal to $i$ in $R$. For purposes of `nacf`, these neighborhoods are calculated using `neighborhood`, with the specified parameters (including dichotomization at `thresh`).

The return value for `nacf` is the selected dependence statistic, calculated for each neighborhood structure from order 0 (the identity) through order `lag.max` (or $N-1$, if `lag.max==NULL`). This vector can be used much like the conventional autocorrelation function, to identify dependencies at various lags. This may, in turn, suggest a starting point for modeling via routines such as `lnam`. 

**neighborhood**

**Value**

A vector containing the dependence statistics (ascending from order 0).

**Author(s)**

Carter T. Butts ⟨buttsc@uci.edu⟩

**References**

**See Also**

geodist, gapply, neighborhood, lnam, acf

**Examples**

```r
#Create a random graph, and an autocorrelated variable
g<-rgraph(50,tp=4/49)
y<-qr.solve(diag(50)-0.8*g,rnorm(50,0,0.05))

#Examine the network autocorrelation function
nacf(g,y)  #Partial neighborhoods
nacf(g,y,partial.neighborhood=FALSE)  #Cumulative neighborhoods

#Repeat, using Moran's I on the underlying graph
nacf(g,y,type="moran")
nacf(g,y,partial.neighborhood=FALSE,type="moran")
```

---

**neighborhood**  
*Compute Neighborhood Structures of Specified Order*

**Description**

For a given graph, returns the specified neighborhood structure at the selected order(s).

**Usage**

```r
neighborhood(dat, order, neighborhood.type = c("in", "out", "total"),
mode = "digraph", diag = FALSE, thresh = 0, return.all = FALSE,
partial = TRUE)
```

**Arguments**

- **dat**  
one or more graphs.
- **order**  
order of the neighborhood to extract.
- **neighborhood.type**  
neighborhood type to employ.
neighborhood

mode "digraph" if dat is directed, otherwise "graph".
diag logical; do the diagonal entries of dat contain valid data?
thresh dichotomization threshold to use for dat; edges whose values are greater than 
thresh are treated as present.
return.all logical; return neighborhoods for all orders up to order?
partial logical; return partial (rather than cumulative) neighborhoods?

Details

The adjacency matrix associated with the $i$th order neighborhood is defined as the identity matrix for 
order 0, and otherwise depends on the type of neighborhood involved. For input graph $G = (V, E)$, 
let the base relation, $R$, be given by the underlying graph of $G$ (i.e., $G \cup G^T$) if total neighborhoods 
are sought, the transpose of $G$ if incoming neighborhoods are sought, or $G$ otherwise. The partial 
neighborhood structure of order $i > 0$ on $R$ is then defined to be the digraph on $V$ whose edge set 
consists of the ordered pairs $(j, k)$ having geodesic distance $i$ in $R$. The corresponding cumulative 
neighborhood is formed by the ordered pairs having geodesic distance less than or equal to $i$ in $R$. 

Neighborhood structures are commonly used to parameterize various types of network autocorrela-

tion models. They may also be used in the calculation of certain types of local structural indices; 
gapply provides an alternative function which can be used for this purpose.

Value

An array or adjacency matrix containing the neighborhood structures (if dat is a single graph); if 
dat contains multiple graphs, then a list of such structures is returned.

```
netcancor

Canonical Correlation for Labeled Graphs

Description

netcancor finds the canonical correlation(s) between the graph sets \( x \) and \( y \), testing the result using either conditional uniform graph (CUG) or quadratic assignment procedure (QAP) null hypotheses.

Usage

```r
netcancor(y, x, mode="digraph", diag=FALSE, nullhyp="cugtie", reps=1000)
```

Arguments

- **y**: one or more input graphs.
- **x**: one or more input graphs.
- **mode**: string indicating the type of graph being evaluated. "digraph" indicates that edges should be interpreted as directed; "graph" indicates that edges are undirected. mode is set to "digraph" by default.
- **diag**: boolean indicating whether or not the diagonal should be treated as valid data. Set this true if and only if the data can contain loops. diag is FALSE by default.
- **nullhyp**: string indicating the particular null hypothesis against which to test the observed estimands. A value of "cug" implies a conditional uniform graph test (see cugtest) controlling for order only; "cugden" controls for both order and tie probability; "cugtie" controls for order and tie distribution (via bootstrap); and "qap" implies that the QAP null hypothesis (see qaptest) should be used.
- **reps**: integer indicating the number of draws to use for quantile estimation. (Relevant to the null hypothesis test only - the analysis itself is unaffected by this parameter.) Note that, as for all Monte Carlo procedures, convergence is slower for more extreme quantiles.

Details

The netcancor routine is actually a front-end to the cancor routine for computing canonical correlations between sets of vectors. netcancor itself vectorizes the network variables (as per its graph type) and manages the appropriate null hypothesis tests; the actual canonical correlation is handled by cancor.

Canonical correlation itself is a multivariate generalization of the product-moment correlation. Specifically, the analysis seeks linear combinations of the variables in \( y \) which are well-explained by linear combinations of the variables in \( x \). The network version of this technique is performed elementwise on the adjacency matrices of the graphs in question; as usual, the result should be interpreted with an eye to the relationship between the type of data used and the assumptions of the underlying model.

Intelligent printing and summarizing of netcancor objects is provided by print.netcancor and summary.netcancor.
An object of class `netcancor` with the following properties:

- `xdist` Array containing the distribution of the X coefficients under the null hypothesis test.
- `ydist` Array containing the distribution of the Y coefficients under the null hypothesis test.
- `cdist` Array containing the distribution of the canonical correlation coefficients under the null hypothesis test.
- `cor` Vector containing the observed canonical correlation coefficients.
- `xcoef` Vector containing the observed X coefficients.
- `ycoef` Vector containing the observed Y coefficients.
- `cpgreq` Vector containing the estimated upper tail quantiles (p>=obs) for the observed canonical correlation coefficients under the null hypothesis.
- `cpleeq` Vector containing the estimated lower tail quantiles (p<=obs) for the observed canonical correlation coefficients under the null hypothesis.
- `xpgreq` Matrix containing the estimated upper tail quantiles (p>=obs) for the observed X coefficients under the null hypothesis.
- `xpleeq` Matrix containing the estimated lower tail quantiles (p<=obs) for the observed X coefficients under the null hypothesis.
- `ypgreq` Matrix containing the estimated upper tail quantiles (p>=obs) for the observed Y coefficients under the null hypothesis.
- `ypleeq` Matrix containing the estimated lower tail quantiles (p<=obs) for the observed Y coefficients under the null hypothesis.
- `cnames` Vector containing names for the canonical correlation coefficients.
- `xnames` Vector containing names for the X vars.
- `ynames` Vector containing names for the Y vars.
- `xcenter` Values used to adjust the X variables.
- `xcenter` Values used to adjust the Y variables.
- `nullhyp` String indicating the null hypothesis employed.

This will eventually be replaced with a superior cancor procedure with more interpretable output; the new version will handle arbitrary labeling as well.

summary(nc)
```

netlm

**Linear Regression for Network Data**

**Description**

`netlm` regresses the network variable in `y` on the network variables in stack `x` using ordinary least squares. The resulting fits (and coefficients) are then tested against the indicated null hypothesis.

**Usage**

```r
netlm(y, x, intercept=TRUE, mode="digraph", diag=FALSE,
      nullhyp=c("qap", "qapspp", "qapy", "qapx", "qapallx",
      "cugtie", "cugden", "cuguman", "classical"),
      test.statistic = c("t-value", "beta"), tol=1e-7,
      reps=1000)
```

**Arguments**

- `y` dependent network variable. This should be a matrix, for obvious reasons; NAs are allowed, but dichotomous data is strongly discouraged due to the assumptions of the analysis.
- `x` stack of independent network variables. Note that NAs are permitted, as is dichotomous data.
- `intercept` logical; should an intercept term be added?
- `mode` string indicating the type of graph being evaluated. "digraph" indicates that edges should be interpreted as directed; "graph" indicates that edges are undirected. `mode` is set to "digraph" by default.
- `diag` logical; should the diagonal be treated as valid data? Set this true if and only if the data can contain loops. `diag` is FALSE by default.
- `nullhyp` string indicating the particular null hypothesis against which to test the observed estimands.
- `test.statistic` string indicating the test statistic to be used for the Monte Carlo procedures.
- `tol` tolerance parameter for `qr.solve`.

Details

netlm performs an OLS linear network regression of the graph $y$ on the graphs in $x$. Network regression using OLS is directly analogous to standard OLS regression elementwise on the appropriately vectorized adjacency matrices of the networks involved. In particular, the network regression attempts to fit the model:

$$A_y = b_0 A_1 + b_1 A_{x_1} + b_2 A_{x_2} + \ldots + Z$$

where $A_y$ is the dependent adjacency matrix, $A_{x_i}$ is the $i$th independent adjacency matrix, $A_1$ is an $n \times n$ matrix of 1’s, and $Z$ is an $n \times n$ matrix of independent normal random variables with mean 0 and variance $\sigma^2$. Clearly, this model is nonoptimal when $A_y$ is dichotomous (or, for that matter, categorical in general); an alternative such as netlogit should be employed in such cases. (Note that netlm will still attempt to fit such data...the user should consider him or herself to have been warned.)

Because of the frequent presence of row/column/block autocorrelation in network data, classical hull hypothesis tests (and associated standard errors) are generally suspect. Further, it is sometimes of interest to compare fitted parameter values to those arising from various baseline models (e.g., uniform random graphs conditional on certain observed statistics). The tests supported by netlm are as follows:

- **classical** tests based on classical asymptotics.
- **cug** conditional uniform graph test (see cugtest) controlling for order.
- **cugden** conditional uniform graph test, controlling for order and density.
- **cugtie** conditional uniform graph test, controlling for order and tie distribution.
- **qap** QAP permutation test (see qaptest); currently identical to qapspp.
- **qapallx** QAP permutation test, using independent x-permutations.
- **qapspp** QAP permutation test, using Dekker’s "semi-partialling plus" procedure.
- **qapx** QAP permutation test, using (single) x-permutations.
- **qapy** QAP permutation test, using y-permutations.

The statistic to be employed in the above tests may be selected via test.statistic. By default, the $t$-statistic (rather than estimated coefficient) is used, as this is more approximately pivotal; coefficient-based tests are not recommended for QAP null hypotheses, although they are provided here for legacy purposes.

Note that interpretation of quantiles for single coefficients can be complex in the presence of multicollinearity or third variable effects. qapspp is generally recommended for most multivariable analyses, as it is known to be fairly robust to these conditions. Reasonable printing and summarizing of netlm objects is provided by print.netlm and summary.netlm, respectively. No plot methods exist at this time, alas.

Value

An object of class netlm
netlogit

Description

netlogit performs a logistic regression of the network variable in \( y \) on the network variables in set \( x \). The resulting fits (and coefficients) are then tested against the indicated null hypothesis.

Usage

\[
\text{netlogit}(y, x, \text{intercept=TRUE, mode="digraph", diag=FALSE, nullhyp=c("qap", "qapspp", "qapy", "qapx", "qapallx", "cugtie", "cugden", "cuguman", "classical"), to1=1e-7, reps=1000)}
\]
Arguments

- **y**: dependent network variable. NAs are allowed, and the data should be dichotomous.
- **x**: the stack of independent network variables. Note that NAs are permitted, as is dichotomous data.
- **intercept**: logical; should an intercept term be fitted?
- **mode**: string indicating the type of graph being evaluated. "digraph" indicates that edges should be interpreted as directed; "graph" indicates that edges are undirected. mode is set to "digraph" by default.
- **diag**: boolean indicating whether or not the diagonal should be treated as valid data. Set this true if and only if the data can contain loops. diag is FALSE by default.
- **nullhyp**: string indicating the particular null hypothesis against which to test the observed estimands.
- **tol**: tolerance parameter for `qr.solve`.
- **reps**: integer indicating the number of draws to use for quantile estimation. (Relevant to the null hypothesis test only – the analysis itself is unaffected by this parameter.) Note that, as for all Monte Carlo procedures, convergence is slower for more extreme quantiles. By default, reps=1000.

Details

`netlogit` is primarily a front-end to the built-in `glm.fit` routine. `netlogit` handles vectorization, sets up `glm` options, and deals with null hypothesis testing; the actual fitting is taken care of by `glm.fit`.

Logistic network regression using is directly analogous to standard logistic regression elementwise on the appropriately vectorized adjacency matrices of the networks involved. As such, it is often a more appropriate model for fitting dichotomous response networks than is linear network regression.

Because of the frequent presence of row/column/block autocorrelation in network data, classical null hypothesis tests (and associated standard errors) are generally suspect. Further, it is sometimes of interest to compare fitted parameter values to those arising from various baseline models (e.g., uniform random graphs conditional on certain observed statistics). The tests supported by `netlogit` are as follows:

- **classical** tests based on classical asymptotics.
- **cug**: conditional uniform graph test (see `cugtest`) controlling for order.
- **cugden**: conditional uniform graph test, controlling for order and density.
- **cugtie**: conditional uniform graph test, controlling for order and tie distribution.
- **qap**: QAP permutation test (see `qaptest`); currently identical to `qapspp`.
- **qapallx**: QAP permutation test, using independent x-permutations.
- **qapspp**: QAP permutation test, using Dekker's "semi-partialling plus" procedure.
- **qapx**: QAP permutation test, using (single) x-permutations.
- **qapy**: QAP permutation test, using y-permutations.

Note that interpretation of quantiles for single coefficients can be complex in the presence of multicollinearity or third variable effects. Although `qapspp` is known to be robust to these conditions in the OLS case, there are no equivalent results for logistic regression. Caution is thus advised. Reasonable printing and summarizing of `netlogit` objects is provided by `print.netlogit` and `summary.netlogit`, respectively. No plot methods exist at this time.
npostpred

**Value**
An object of class `netlogit`

#Create a response structure
y.l<-x[1,,]+4*x[2,,]+2*x[3,,]  #Note that the fourth graph is unrelated
y.p<-apply(y.l, c(1, 2), function(a){1/(1+exp(-a)))
y<-rgraph(20, tprob=y.p)

#Fit a netlogit model
nl<-netlogit(y, x, reps=100)

#Examine the results
summary(nl)
```

---

**npostpred**

*Take Posterior Predictive Draws for Functions of Networks*

**Description**

`npostpred` takes a list or data frame, `b`, and applies the function `FUN` to each element of `b`'s `net` member.

**Usage**

`npostpred(b, FUN, ...)`

**Arguments**

- **b**  
  A list or data frame containing posterior network draws; these draws must take the form of a graph stack, and must be the member of `b` referenced by "net"

- **FUN**  
  Function for which posterior predictive is to be estimated

- **...**  
  Additional arguments to `FUN`
Details

Although created to work with `bbnam`, `npostpred` is quite generic. The form of the posterior draws will vary with the output of `FUN`; since invocation is handled by `apply`, check there if unsure.

Value

A series of posterior predictive draws

Author(s)

Carter T. Butts (buttsc@uci.edu)

References

See Also

`bbnam`

Examples

```r
# Create some random data
g <- rgraph(5)
g.p <- 0.8 * g + 0.2 * (1 - g)
dat <- rgraph(5, 5, tprob = g.p)

# Define a network prior
pnet <- matrix(ncol = 5, nrow = 5)
pnet[, ,] <- 0.5
# Define em and ep priors
pem <- matrix(nrow = 5, ncol = 2)
pem[, , 1] <- 3
pem[, , 2] <- 5
pep <- matrix(nrow = 5, ncol = 2)
pep[, , 1] <- 3
pep[, , 2] <- 5

# Draw from the posterior
b <- bbnam(dat, model = "actor", nprior = pnet, emprior = pem, epprior = pep,
           burntime = 100, draws = 100)
# Plot a summary of the posterior predictive of reciprocity
hist(npostpred(b, g reciprocity))
```

---

### nties

Find the Number of Possible Ties in a Given Graph or Graph Stack

#### Description

`nties` returns the number of possible edges in each element of `dat`, given `mode` and `diag`. 
Usage

```r	neties(dat, mode="digraph", diag=FALSE)
```

Arguments

dat a graph or set thereof.
mode one of “digraph”, “graph”, and “hgraph”.
diag a boolean indicating whether or not diagonal entries (loops) should be treated as valid data; ignored for hypergraphic (“hgraph”) data.

Details

`nties` is used primarily to automate maximum edge counts for use with normalization routines.

Value

The number of possible edges, or a vector of the same

Note

For two-mode (hypergraphic) data, the value returned isn’t technically the number of edges per se, but rather the number of edge memberships.

Author(s)

Carter T. Butts (buttsc@uci.edu)

Examples

```r
# How many possible edges in a loopless digraph of order 15?
nties(rgraph(15), diag=FALSE)
```

---

**numperm**

*Get the nth Permutation Vector by Periodic Placement*

Description

`numperm` implicitly numbers all permutations of length `olength`, returning the `permnum`th of these.

Usage

```r
numperm(olength, permnum)
```

Arguments

- `olength` The number of items to permute
- `permnum` The number of the permutation to use (in `1:olength!`)
Details

The \( n! \) permutations on \( n \) items can be deterministically ordered via a factorization process in which there are \( n \) slots for the first element, \( n-1 \) for the second, and \( n-i \) for the \( i \)th. This fact is quite handy if you want to visit each permutation in turn, or if you wish to sample without replacement from the set of permutations on some number of elements: one just enumerates or samples from the integers on \([1,n!]\), and then find the associated permutation. \texttt{numperm} performs exactly this last operation, returning the \( \text{permnum} \)th permutation on \( \text{olength} \) items.

Value

A permutation vector

Note

Permutation search is central to the estimation of structural distances, correlations, and covariances on partially labeled graphs. \texttt{numperm} is hence used by \texttt{structdist}, \texttt{gscor}, \texttt{gscov}, etc.

Author(s)

Carter T. Butts (buttsc@uci.edu)

See Also

\texttt{rperm}, \texttt{rmperm}

Examples

```r
# Draw a graph
g <- rgraph(5)

# Permute the rows and columns
p.1 <- numperm(5, 1)
p.2 <- numperm(5, 2)
p.3 <- numperm(5, 3)
g[p.1, p.1]
g[p.2, p.2]
g[p.3, p.3]
```

Description

Generates various plots of posterior draws from the \texttt{bbnam} model.

Usage

```r
## S3 method for class 'bbnam':
plot(x, mode="density", intlines=TRUE, ...)
```
Arguments

- **x**: A `bbnam` object
- **mode**: “density” for kernel density estimators of posterior marginals; otherwise, histograms are used
- **intlines**: Plot lines for the 0.9 central posterior probability intervals?
- **...**: Additional arguments to `plot`

Details

`plot.bbnam` provides plots of the estimated posterior marginals for the criterion graph and error parameters (as appropriate). Plotting may run into difficulties when dealing with large graphs, due to the problem of getting all of the various plots on the page; the routine handles these issues reasonably intelligently, but there is doubtless room for improvement.

Examples

```r
#Create some random data
g<-rgraph(5)
g.p<-0.8*g+0.2*(1-g)
dat<-rgraph(5,5,tprob=g.p)

#Define a network prior
pnet<-matrix(ncol=5,nrow=5)
pnet[,]<-0.5

#Define em and ep priors
pem<-matrix(nrow=5,ncol=2)
pem[,1]<-3
pem[,2]<-5
pep<-matrix(nrow=5,ncol=2)
pep[,1]<-3
pep[,2]<-5

#Draw from the posterior
b<-bbnam(dat,model="actor",nprior=pnet,emprior=pem,epprior=pep,
burntime=100,draws=100)

#Print a summary of the posterior draws
summary(b)
```
# Plot the result
```r
plot(b)
```

---

**Description**

Displays a plot of the blocked data matrix, given a blockmodel object.

**Usage**

```r
## S3 method for class 'blockmodel':
plot(x, ...)
```

**Arguments**

- `x` An object of class `blockmodel`
- `...` Further arguments passed to or from other methods

**Details**

Plots of the blocked data matrix (i.e., the data matrix with rows and columns permuted to match block membership) can be useful in assessing the strength of the block solution (particularly for clique detection and/or regular equivalence).

**Value**

None

`blockmodel`, `plot.sociomatrix`
Examples

```r
# Create a random graph with _some_ edge structure
g.p <- sapply(runif(20, 0, 1), rep, 20)  # Create a matrix of edge
# probabilities

g <- rgraph(20, tprob = g.p)  # Draw from a Bernoulli graph
# distribution

# Cluster based on structural equivalence
eq <- equiv.clust(g)

# Form a blockmodel with distance relaxation of 10
b <- blockmodel(g, eq, h = 10)
plot(b)  # Plot it
```

Description

Plots the distribution of a CUG test statistic.

Usage

```r
## S3 method for class 'cugtest':
plot(x, mode = "density", ...)  
```

Arguments

- `x`: A `cugtest` object
- `mode`: "density" for kernel density estimation, "hist" for histogram
- `...`: Additional arguments to `plot`

Details

In addition to the quantiles associated with a CUG test, it is often useful to examine the form of the distribution of the test statistic. `plot.cugtest` facilitates this.

**plot.equiv.clust**  
*Plot an equiv.clust Object*

### Description

Plots a hierarchical clustering of node positions as generated by `equiv.clust`.

### Usage

```r
## S3 method for class 'equiv.clust':
plot(x, labels = NULL, ...)  
```

### Arguments

- `x`  
  An `equiv.clust` object

- `labels`  
  A vector of vertex labels

- `...`  
  Additional arguments to `plot.hclust`

### Details

`plot.equiv.clust` is actually a front-end to `plot.hclust`; see the latter for more additional documentation.

### Value

None.

### plot.sociomatrix

**Plot Matrices Using a Color/Intensity Grid**

#### Description

Plots a matrix, `m`, associating the magnitude of the i,jth cell of `m` with the color of the i,jth cell of an `nrow(m)` by `ncol(m)` grid.

#### Usage

```r
## S3 method for class 'sociomatrix':
plot(x, labels=NULL, drawlab=TRUE, diaglab=TRUE,
     drawlines=TRUE, xlab=NULL, ylab=NULL, cex.lab=1, ...)

sociomatrixplot(x, labels=NULL, drawlab=TRUE, diaglab=TRUE,
     drawlines=TRUE, xlab=NULL, ylab=NULL, cex.lab=1, ...)
```

#### Arguments

- `x`  
an input graph.
- `labels`  
a list containing the vectors of row and column labels (respectively); defaults to numerical labels.
- `drawlab`  
logical; add row/column labels to the plot?
- `diaglab`  
logical; label the diagonal?
- `drawlines`  
logical; draw lines to mark cell boundaries?
- `xlab`  
x axis label.
- `ylab`  
y axis label.
- `cex.lab`  
optional expansion factor for labels.
- `...`  
additional arguments to `plot`.
Details

plot.sociomatrix is particularly valuable for examining large adjacency matrices, whose structure can be non-obvious otherwise. sociomatrixplot is an alias to plot.sociomatrix, and may eventually supersede it.

#Plot a much larger one
plot.sociomatrix(rgraph(100),drawlab=FALSE,diaglab=FALSE)

desc

Description

Computes Gelman and Rubin’s (simplified) measure of scale reduction for draws of a single scalar estimand from parallel MCMC chains.

Usage

potscalered.mcmc(psi)

Arguments

psi An nxm matrix, with columns corresponding to chains and rows corresponding to iterations.

Details

The Gelman and Rubin potential scale reduction (\(\sqrt{R}\)) provides an ANOVA-like comparison of the between-chain to within-chain variance on a given scalar estimand; the disparity between these gives an indication of the extent to which the scale of the simulated distribution can be reduced via further sampling. As the parallel chains converge, \(\sqrt{R}\) approaches 1 (from above), and it is generally recommended that values of 1.2 or less be obtained before a series of draws can be considered well-mixed. (Even so, one should ideally examine other indicators of chain mixing, and verify that the properties of the draws are as they should be. There is currently no fool-proof way to verify burn-in
of an MCMC, but using multiple indicators should help one avoid falling prey to the idiosyncrasies of any one index.)

Note that the particular estimators used in the $\sqrt{R}$ formulation are based on normal-theory results, and as such have been criticized vis a vis their behavior on other distributions. Where simulating distributions whose properties differ greatly from the normal, an alternative form of the measure using robust measures of scale (e.g., the IQR) may be preferable.

**Value**

The potential scale reduction measure

**prestige**

*Calculate the Vertex Prestige Scores*

**Description**

`prestige` takes one or more graphs (`dat`) and returns the prestige scores of positions (selected by `nodes`) within the graphs indicated by `g`. Depending on the specified mode, prestige based on any one of a number of different definitions will be returned. This function is compatible with `centralization`, and will return the theoretical maximum absolute deviation (from maximum) conditional on size (which is used by `centralization` to normalize the observed centralization score).

**Usage**

```r
prestige(dat, g=1, nodes=NULL, gmode="digraph", diag=FALSE, 
          cmode="indegree", tmaxdev=FALSE, rescale=FALSE, tol=1e-07)
```

**Arguments**

- `dat`: one or more input graphs.
- `g`: integer indicating the index of the graph for which centralities are to be calculated (or a vector thereof). By default, `g==1`.
- `nodes`: vector indicating which nodes are to be included in the calculation. By default, all nodes are included.
"Prestige" is the name collectively given to a range of centrality scores which focus on the extent to which one is nominated by others. The definitions supported here are as follows:

1. indegree: indegree centrality
2. indegree.rownorm: indegree within the row-normalized graph
3. indegree.rowcolnorm: indegree within the row-column normalized graph
4. eigenvector: eigenvector centrality within the transposed graph (i.e., incoming ties recursively determine prestige)
5. eigenvector.rownorm: eigenvector centrality within the transposed row-normalized graph
6. eigenvector.colnorm: eigenvector centrality within the transposed column-normalized graph
7. eigenvector.rowcolnorm: eigenvector centrality within the transposed row/column-normalized graph
8. domain: indegree within the reachability graph (Lin’s unweighted measure)
9. domain.proximity: Lin’s proximity-weighted domain prestige

Note that the centralization of prestige is simply the extent to which one actor has substantially greater prestige than others; the underlying definition is the same.

Value

A vector, matrix, or list containing the prestige scores (depending on the number and size of the input graphs).

Warning

Making adjacency matrices doubly stochastic (row-column normalization) is not guaranteed to work. In general, be wary of attempting to try normalizations on graphs with degenerate rows and columns.

**Description**

Fits a $p^*$/ERG model to the graph in `dat` containing the effects listed in `effects`. The result is returned as a `glm` object.

**Usage**

```r
pstar(dat, effects=c("choice", "mutuality", "density", "reciprocity", "stransitivity", "wtransitivity", "stranstri", "wtranstri", "outdegree", "indegree", "betweenness", "closeness", "degcenentralization", "betcenralization", "clocenralization", "connectedness", "hierarchy", "lubness", "efficiency"), attr=NULL, memb=NULL, diag=FALSE, mode="digraph")
```

**Arguments**

- `dat`: a single graph
- `effects`: a vector of strings indicating which effects should be fit.
- `attr`: a matrix whose columns contain individual attributes (one row per vertex) whose differences should be used as supplemental predictors.
- `memb`: a matrix whose columns contain group memberships whose categorical similarities (same group/not same group) should be used as supplemental predictors.
- `diag`: a boolean indicating whether or not diagonal entries (loops) should be counted as meaningful data.
- `mode`: "digraph" if `dat` is directed, else "graph"

**Details**

$p^*$ (also called the Exponential Random Graph (ERG) family) is an exponential family specification for network data. Under $p^*$, it is assumed that

$$p(G = g) \propto \exp(\beta_0 \gamma_0(g) + \beta_1 \gamma_1(g) + \ldots)$$

for all $g$, where the betas represent real coefficients and the gammas represent functions of $g$. Unfortunately, the unknown normalizing factor in the above expression makes evaluation difficult in the general case. One solution to this problem is to operate instead on the edgewise log odds; in this case, the $p^*$ MLE can be approximated by a logistic regression of each edge on the differences in the gamma scores induced by the presence and absence of said edge in the graph (conditional on all other edges). It is this approximation (known as autologistic regression, or maximum pseudo-likelihood estimation) which is employed here.

Using the `effects` argument, a range of different potential parameters can be estimated. The network measure associated with each is, in turn, the edge-perturbed difference in:
1. choice: the number of edges in the graph (acts as a constant)
2. mutuality: the number of reciprocated dyads in the graph
3. density: the density of the graph
4. reciprocity: the edgewise reciprocity of the graph
5. stransitivity: the strong transitivity of the graph
6. wtransitivity: the weak transitivity of the graph
7. transtri: the number of strongly transitive triads in the graph
8. transtri: the number of weakly transitive triads in the graph
9. outdegree: the outdegree of each actor (|V| parameters)
10. indegree: the indegree of each actor (|V| parameters)
11. betweenness: the betweenness of each actor (|V| parameters)
12. closeness: the closeness of each actor (|V| parameters)
13. degcentralization: the Freeman degree centralization of the graph
14. betcentralization: the betweenness centralization of the graph
15. clocentralization: the closeness centralization of the graph
16. connectedness: the Krackhardt connectedness of the graph
17. hierarchy: the Krackhardt hierarchy of the graph
18. efficiency: the Krackhardt efficiency of the graph
19. lubness: the Krackhardt LUBness of the graph

(Note that some of these do differ somewhat from the common p* parameter formulation, e.g. quantities such as density and reciprocity are computed as per the \texttt{gden} and \texttt{grecip} functions rather than via the unnormalized "choice" and "mutual" quantities one often finds in the p* literature.) \textit{Please do not attempt to use all effects simultaneously}!!! In addition to the above, the user may specify a matrix of individual attributes whose absolute dyadic differences are to be used as predictors, as well as a matrix of individual memberships whose dyadic categorical similarities (same/different) are used in the same manner.

Although the p* framework is quite versatile in its ability to accommodate a range of structural predictors, it should be noted that the substantial collinearity of many of the standard p* predictors can lead to very unstable model fits. Measurement and specification errors compound this problem; thus, it is somewhat risky to use p* in an exploratory capacity (i.e., when there is little prior knowledge to constrain choice of parameters). While raw instability due to multicollinearity should decline with graph size, improper specification will still result in biased coefficient estimates so long as an omitted predictor correlates with an included predictor. Caution is advised.

\textbf{Value}

A \texttt{glm} object

\textbf{WARNING}

Estimation of p* models by maximum pseudo-likelihood is now known to be a dangerous practice. Use at your own risk.

\textbf{Note}

In the long run, support will be included for p* models involving arbitrary functions (much like the system used with \texttt{cugtest} and \texttt{qaptest}).

qaptest  Perform Quadratic Assignment Procedure (QAP) Hypothesis Tests for Graph-Level Statistics

Description
qaptest tests an arbitrary graph-level statistic (computed on dat by FUN) against a QAP null hypothesis, via Monte Carlo simulation of likelihood quantiles. Note that fair amount of flexibility is possible regarding QAP tests on functions of such statistics (see an equivalent discussion with respect to CUG null hypothesis tests in Anderson et al. (1999)). See below for more details.

Usage
qaptest(dat, FUN, reps=1000, ...)
Arguments

- `dat` graphs to be analyzed. Though one could in principle use a single graph, this is rarely if ever sensible in a QAP-test context.
- `FUN` function to generate the test statistic. `FUN` must accept `dat` and the specified `g` arguments, and should return a real number.
- `reps` integer indicating the number of draws to use for quantile estimation. Note that, as for all Monte Carlo procedures, convergence is slower for more extreme quantiles. By default, `reps=1000`.

Details

The null hypothesis of the QAP test is that the observed graph-level statistic on graphs $G_1, G_2, \ldots$ was drawn from the distribution of said statistic evaluated (uniformly) on the set of all relabelings of $G_1, G_2, \ldots$. Pragmatically, this test is performed by repeatedly (randomly) relabeling the input graphs, recalculating the test statistic, and then evaluating the fraction of draws greater than or equal to (and less than or equal to) the observed value. This accumulated fraction approximates the integral of the distribution of the test statistic over the set of unlabeled input graphs.

The `qaptest` procedure returns a `qaptest` object containing the estimated likelihood (distribution of the test statistic under the null hypothesis), the observed value of the test statistic on the input data, and the one-tailed p-values (estimated quantiles) associated with said observation. As usual, the (upper tail) null hypothesis is rejected for significance level alpha if $p>=\text{observation}$ is less than alpha (or $p<=\text{observation}$, for the lower tail); if the hypothesis is undirected, then one rejects if either $p<=\text{observation}$ or $p>=\text{observation}$ is less then alpha/2. Standard caveats regarding the use of null hypothesis testing procedures are relevant here: in particular, bear in mind that a significant result does not necessarily imply that the likelihood ratio of the null model and the alternative hypothesis favors the latter.

In interpreting a QAP test, it is important to bear in mind the nature of the QAP null hypothesis. The QAP test should not be interpreted as evaluating underlying structural differences; indeed, QAP is more accurately understood as testing differences induced by a particular vertex labeling controlling for underlying structure. Where there is substantial automorphism in the underlying structures, QAP will tend to given non-significant results. (In fact, it is impossible to obtain a one-tailed significance level in excess of $\max_{g \in \{G, H\}} \frac{|\text{Aut}(g)|}{|\text{Perm}(g)|}$ when using a QAP test on a bivariate graph statistic $f(G, H)$, where $\text{Aut}(g)$ and $\text{Perm}(g)$ are the automorphism and permutation groups on $g$, respectively. This follows from the fact that all members of $\text{Aut}(g)$ will induce the same values of $f()$.) By turns, significance under QAP does not necessarily imply that the observed structural relationship is unusual relative to what one would expect from typical structures with (for instance) the sizes and densities of the graphs in question. In contexts in which one’s research question implies a particular labeling of vertices (e.g., "within this group of individuals, do friends also tend to give advice to one another"), QAP can be a very useful way of ruling out spurious structural influences (e.g., some respondents tend to indiscriminately nominate many people (without regard to whom), resulting in a structural similarity which has nothing to do with the identities of those involved). Where one’s question does not imply a labeled relationship (e.g., is the shape of this group’s friendship network similar to that of its advice network), the QAP null hypothesis is inappropriate.

Value

An object of class `qaptest`, containing

- `testval` The observed value of the test statistic.
- `dist` A vector containing the Monte Carlo draws.
reachability

Description

reachability takes one or more (possibly directed) graphs as input, producing the associated reachability matrices.

Usage

reachability(dat, geodist.precomp=NULL)
Arguments

dat
  one or more graphs (directed or otherwise).

g geodist.precomp
  optionally, a precomputed geodist object.

Details

For a digraph $G = (V,E)$ with vertices $i$ and $j$, let $P_{ij}$ represent a directed $ij$ path. Then the graph

$$R = (V(G), \{(i,j) : i,j \in V(G), P_{ij} \in G\})$$

is said to be the reachability graph of $G$, and the adjacency matrix of $R$ is said to be $G$’s reachability matrix. (Note that when $G$ is undirected, we simply take each undirected edge to be bidirectional.) Vertices which are adjacent in the reachability graph are connected by one or more directed paths in the original graph; thus, structural equivalence classes in the reachability graph are synonymous with strongly connected components in the original structure.

Bear in mind that – as with all matters involving connectedness – reachability is strongly related to size and density. Since, for any given density, almost all structures of sufficiently large size are connected, reachability graphs associated with large structures will generally be complete. Measures based on the reachability graph, then, will tend to become degenerate in the large $|V(G)|$ limit (assuming constant positive density).

Value

A reachability matrix

**read.dot**  
*Read Graphviz DOT Files*

**Description**
Reads network information in Graphviz’s DOT format, returning an adjacency matrix.

**Usage**
```r
read.dot(...) 
```

**Arguments**
- `...`  
The name of the file whence to import the data, or else a connection object (suitable for processing by `readLines`).

**Details**
The Graphviz project’s DOT language is a simple but flexible tool for describing graphs. See the included reference for details.

**Value**
The imported graph, in adjacency matrix form.

**Author(s)**
Matthijs den Besten (matthijs.denbesten@gmail.com)

**See Also**
- `read.nos`, `write.nos`, `write.dl` 

---

**read.nos**  
*Read (N)eo-(O)rg(S)tat Input Files*

**Description**
Reads an input file in NOS format, returning the result as a graph set.

**Usage**
```r
read.nos(file, return.as.edgelist = FALSE) 
```
Arguments

file the file to be imported
return.as.edgelist logical; should the resulting graphs be returned in sna edgelist format?

Details

NOS format consists of three header lines, followed by a whitespace delimited stack of raw adjacency matrices; the format is not particularly elegant, but turns up in certain legacy applications (mostly at CMU). read.nos provides a quick and dirty way of reading in these files, without the headache of messing with read.table settings.

The content of the NOS format is as follows:

$m$
$n$ $o$
$<kr1> <kr2> ... <krn> <kc1> ... <kcn>
$<a111> <a112> ... <a11o>
$<a121> <a122> ... <a12o>
...
$<a1n1> <a1n2> ... <a1no>
$<a211> <a212> ... <a21o>
...
$<a2n1> <a2n2> ... <a2no>
...
$<amn1> <amn2> ... <amno>

where $<abcd>$ is understood to be the value of the c->d edge in the bth graph of the file. (As one might expect, m, n, and o are the numbers of graphs (matrices), rows, and columns for the data, respectively.) The "k" line contains a list of row and column "colors", categorical variables associated with each row and column, respectively. Although originally intended to communicate exchangability information, these can be used for other purposes (though there are easier ways to deal with attribute data these days).

Value

The imported graph set (in adjacency array or edgelist form).

Note

read.nos currently ignores the coloring information.

redist

Find a Matrix of Distances Between Positions Based on Regular Equivalence

Description

redist uses the graphs indicated by g in dat to assess the extent to which each vertex is regularly equivalent; method determines the measure of approximate equivalence which is used (currently, only CATREGE).

Usage

redist(dat, g = NULL, method = c("catrege"), mode = "digraph", diag = FALSE, seed.partition = NULL, code.diss = TRUE, ...)

Arguments

dat a graph or set thereof.
g a vector indicating which elements of dat should be examined (by default, all are used).
method method to use when assessing regular equivalence (currently, only "catrege").
mode "digraph" for directed data, otherwise "graph".
diag logical; should diagonal entries (loops) should be treated as meaningful data?
seed.partition optionally, an initial equivalence partition to “seed” the CATREGE algorithm.
code.diss logical; return as dissimilarities (rather than similarities)?
... additional parameters (currently ignored).

Details

redist provides a basic tool for assessing the (approximate) regular equivalence of actors. Two vertices i and j are said to be regularly equivalent with respect to role assignment r if \{r(u) : u ∈ N^+(i)\} = \{r(u) : u ∈ N^+(j)\} and \{r(u) : u ∈ N^-(i)\} = \{r(u) : u ∈ N^-(j)\}, where N^+ and N^- denote out- and in-neighborhoods (respectively). RE similarity/difference scores are computed by method, currently Borgatti and Everett’s CATREGE algorithm (which is based on the multiplex maximal regular equivalence on G and its transpose). The “distance” between positions in this case is the inverse of the number of iterative refinements of the initial equivalence (i.e., role) structure required to allocate the positions to regularly equivalent roles (with 0 indicating positions which ultimately belong in the same role). By default, the initial equivalence structure is one in which all vertices are treated as occupying the same role; the seed.partition option can be used to impose alternative constraints. From this initial structure, vertices within the same role having non-identical mixes of neighbor types are re-allocated to different roles (where “neighbor type” is initially due to the pattern of (possibly valued) in- and out-ties, cross-classified by current alter type). This procedure is then iterated until no further division of roles is necessary to satisfy the regularity condition.

Once the similarities/differences are calculated, the results can be used with a clustering routine (such as equiv.clust) or an MDS (such as cmdscale) to identify the underlying role structure.
Value

A matrix of similarity/difference scores.

Note

The maximal regular equivalence is often very uninteresting (i.e., degenerate) for unvalued, undirected graphs. An exogenous constraint (e.g., via the seed.partition) may be required to uncover a more useful refinement of the unconstrained maximal equivalence.

```

rgbn  

*Draw from a Skvoretz-Fararo Biased Net Process*

Description

Produces a series of draws from a Skvoretz-Fararo biased net process using a Gibbs sampler or exact sampling procedure.

Usage

```r
rgbn(n, nv, param = list(pi=0, sigma=0, rho=0, d=0.5),
    burn = nv*nv*5*100, thin = nv*nv*5, maxiter = Inf,
    method = c("mcmc","cftp"), return.as.edgelist = FALSE)
```
Arguments

- **n**: number of draws to take.
- **nv**: number of vertices in the graph to be simulated.
- **param**: a list containing the biased net parameters.
- **burn**: for the Gibbs sampler, the number of burn-in draws to take (and discard).
- **thin**: the thinning parameter for the Gibbs sampler.
- **maxiter**: for the CFTP method, the number of iterations to try before giving up.
- **method**: "mcmc" for the Gibbs sampler, or "cftp" for the exact sampling procedure.
- **return.as.edgelist**: logical; should the simulated draws be returned in edgelist format?

Details

The biased net model stems from early work by Rapoport, who attempted to model networks via a hypothetical “tracing” process. This process may be described loosely as follows. One begins with a small “seed” set of vertices, each member of which is assumed to nominate (generate ties to) other members of the population with some fixed probability. These members, in turn, may nominate new members of the population, as well as members who have already been reached. Such nominations may be “biased” in one fashion or another, leading to a non-uniform growth process.

While the original biased net model depends upon the tracing process, a local interpretation has been put forward by Skvoretz and colleagues in recent years. Using the standard four-parameter process, the conditional probability of an \((i,j)\) edge given all other edges in a random graph \(G\) can be written as

\[
\Pr(i \rightarrow j) = 1 - (1 - \rho)^x(1 - \sigma)^y(1 - \pi)^z(1 - d)
\]

where \(x = 1\) iff \(j \rightarrow i\) (and 0 otherwise), \(y\) is the number of vertices \(k \neq i, j\) such that \(k \rightarrow i, k \rightarrow j\), and \(z = 1\) iff \(x = 1\) and \(y > 0\) (and 0 otherwise). Thus, \(x\) is the number of parent bias events, \(y\) is the number of sibling bias events, and \(z\) is the number of double role bias events. \(d\) is the probability of the baseline edge event; note that an edge arises if the baseline event or any bias event occurs, and all events are assumed conditionally independent. Written in this way, it is clear that the edges of \(G\) are conditionally independent if they share no endpoint. Thus, the above model is a subfamily of the Markov graphs.

It should be noted that the above process is not entirely consistent with the tracing-based model, which is itself not uniformly well-specified in the literature. For this reason, the local model is referred to here as a Skvoretz-Fararo graph process. One significant advantage of this process is that it is well-defined, and easily simulated: the above equation can be used to form the basis of a Gibbs sampler, which is used by `rgbn` to take draws from the (local) biased net model. Burn-in and thinning are controlled by the corresponding arguments; since degeneracy is common with models of this type, it is advisable to check for adequate mixing. An alternative simulation strategy is the exact sampling procedure of Butts (2008), which employs a form of coupling from the past (CFTP). The CFTP method generates exact, independent draws (up to numerical limits), but can be slow to attain coalescence. Setting \(\text{maxiter} < \text{Inf}\) limits the search depth employed, at the possible cost of biasing the resulting sample.

Value

An adjacency array containing the simulated graphs.
rgnm

**Draw Density-Conditioned Random Graphs**

**Description**

`rgnm` generates random draws from a density-conditioned uniform random graph distribution.

**Usage**

```r
gnm(n, nv, m, mode = "digraph", diag = FALSE, return.as.edgelist = FALSE)
```

**Arguments**

- **n**
  - the number of graphs to generate.
- **nv**
  - the size of the vertex set (|V(G)|) for the random graphs.
- **m**
  - the number of edges on which to condition.
- **mode**
  - "digraph" for directed graphs, or "graph" for undirected graphs.

**Examples**

```r
#Generate draws with low density and no biases
g1 <- rgnm(50, 10, param = list(pi = 0, sigma = 0, rho = 0, d = 0.17))
apply(dyad.census(g1), 2, mean) #Examine the dyad census

#Add a reciprocity bias
g2 <- rgnm(50, 10, param = list(pi = 0.5, sigma = 0, rho = 0, d = 0.17))
apply(dyad.census(g2), 2, mean) #Compare with g1

#Alternately, add a sibling bias
g3 <- rgnm(50, 10, param = list(pi = 0.0, sigma = 0.3, rho = 0, d = 0.17))
mean(gtrans(g3)) #Compare transitivity scores
mean(gtrans(g1))
```
rgnm

diag logical; should loops be allowed?
return.as.edgelist logical; should the resulting graphs be returned in edgelist form?

Details

rgnm returns draws from the density-conditioned uniform random graph first popularized by the famous work of Erdos and Renyi (the $G(N, M)$ process). In particular, the pmf of a $G(N, M)$ process is given by

$$ p(G = g | N, M) = \binom{E_m}{M}^{-1} $$

where $E_m$ is the maximum number of edges in the graph. ($E_m$ is equal to $\nu \times (\nu - \text{diag}) / (1 + (\text{mode}==\text{"graph"}))$.)

The $G(N, M)$ process is one of several processes which are used as baseline models of social structure. Other well-known baseline models include the Bernoulli graph (the $G(N, p)$ model of Erdos and Renyi) and the U|MAN model of dyadic independence. These are implemented within sna as rgraph and rgnm, respectively.

Value

A matrix or array containing the drawn adjacency matrices

Note

The famous mathematicians referenced in this man page now have misspelled names, due to R’s difficulty with accent marks.

```r
# Draw 5 random graphs of order 10
all(gden(rgnm(5,10,9,mode="graph"))==-0.2) # Density 0.2
all(gden(rgnm(5,10,9))==0.1) # Density 0.1

# Plot a random graph
gplot(rgnm(1,10,20))
```
rgnmix 

**Draw Mixing-Conditioned Random Graphs**

**Description**

rgnmix generates random draws from a mixing-conditioned uniform random graph distribution.

**Usage**

```r
rgnmix(n, tv, mix, mode = "digraph", diag = FALSE,
       method = c("probability", "exact"), return.as.edgelist = FALSE)
```

**Arguments**

- `n` the number of graphs to generate.
- `tv` a vector of types or classes (one entry per vertex), corresponding to the rows and columns of `mix`. (Note that the total number of vertices generated will be `length(tv)`.)
- `mix` a class-by-class mixing matrix, containing either mixing rates (for `method="probability"`) or edge counts (for `method="exact"`).
- `mode` "digraph" for directed graphs, or "graph" for undirected graphs.
- `diag` logical; should loops be allowed?
- `method` the generation method to use. "probability" results in a Bernoulli edge distribution (conditional on the underlying rates), while "exact" results in a uniform draw conditional on the exact per-block edge distribution.
- `return.as.edgelist` logical; should the resulting graphs be returned in sna edgelist form?

**Details**

The generated graphs (in either adjacency or edgelist form).

**Value**

rgnmix draws from a simple generalization of the Erdos-Renyi N,M family (and the related N,p family), generating graphs with fixed expected or realized mixing rates. Mixing is determined by the `mix` argument, which must contain a class-by-class matrix of mixing rates (either edge probabilities or number of realized edges). The class for each vertex is specified in `tv`, whose entries must correspond to the rows and columns of `mix`. The resulting functionality is much like `blockmodel.expand`, although more general (and in some cases more efficient).

**rgraph**

*Generate Bernoulli Random Graphs*

**Description**

rgraph generates random draws from a Bernoulli graph distribution, with various parameters for controlling the nature of the data so generated.

**Usage**

```r
rgraph(n, m=1, tprob=0.5, mode="digraph", diag=FALSE, replace=FALSE, tielist=NULL, return.as.edgelist=FALSE)
```

**Arguments**

- **n**: The size of the vertex set (|V(G)|) for the random graphs
- **m**: The number of graphs to generate
- **tprob**: Information regarding tie (edge) probabilities; see below
- **mode**: “digraph” for directed data, “graph” for undirected data
- **diag**: Should the diagonal entries (loops) be set to zero?
- **replace**: Sample with or without replacement from a tie list (ignored if tielist==NULL)
- **tielist**: A vector of edge values, from which the new graphs should be bootstrapped
- **return.as.edgelist**: logical; should the resulting graphs be returned in edgelist form?

**Details**

rgraph is a reasonably versatile routine for generating random network data. The graphs so generated are either Bernoulli graphs (graphs in which each edge is a Bernoulli trial, independent conditional on the Bernoulli parameters), or are bootstrapped from a user-provided edge distribution (very handy for CUG tests). In the latter case, edge data should be provided using the tielist argument; the exact form taken by the data is irrelevant, so long as it can be coerced to a vector. In the former case, Bernoulli graph probabilities are set by the tprob argument as follows:

**Examples**

```r
#Draw a random mixing matrix
mix<-matrix(runif(9),3,3)

#Generate a graph with 4 members per class
g<-rgnmix(1,rep(1:3,each=4),mix)
plot.sociomatrix(g)  #Visualize the result

#Repeat the exercise, using the exact method
mix2<-round(mix*8)  #Draw an exact matrix

g<-rgnmix(1,rep(1:3,each=4),mix2,method="exact")
plot.sociomatrix(g)
```

**See Also**

rguman, rgnm, blockmodel.expand
1. If `tprob` contains a single number, this number is used as the probability of all edges.
2. If `tprob` contains a vector, each entry is assumed to correspond to a separate graph (in order). Thus, each entry is used as the probability of all edges within its corresponding graph.
3. If `tprob` contains a matrix, then each entry is assumed to correspond to a separate edge. Thus, each entry is used as the probability of its associated edge in each graph which is generated.
4. Finally, if `tprob` contains a three-dimensional array, then each entry is assumed to correspond to a particular edge in a particular graph, and is used as the associated probability parameter.

Finally, note that `rgraph` will symmetrize all generated networks if `mode` is set to “graph” by copying down the upper triangle. The lower half of `tprob`, where applicable, must still be specified, however.

**Value**

A graph stack

**Note**

The famous mathematicians referenced in this man page now have misspelled names, due to R’s difficulty with accent marks.

**Examples**

```r
#Generate three graphs with different densities
g<-rgraph(10,3,tprob=c(0.1,0.9,0.5))

#Generate from a matrix of Bernoulli parameters
g.p<-matrix(runif(25,0,1),nrow=5)
g<-rgraph(5,2,tprob=g.p)
```
**rguman**  

*Draw Dyad Census-Conditioned Random Graphs*

**Description**

`rguman` generates random draws from a dyad census-conditioned uniform random graph distribution.

**Usage**

```r
guman(n, nv, mut = 0.25, asym = 0.5, null = 0.25,  
method = c("probability", "exact"), return.as.edgelist = FALSE)
```

**Arguments**

- `n`: the number of graphs to generate.
- `nv`: the size of the vertex set (|V(G)|) for the random graphs.
- `mut`: if `method="probability"`, the probability of obtaining a mutual dyad; otherwise, the number of mutual dyads.
- `asym`: if `method="probability"`, the probability of obtaining an asymmetric dyad; otherwise, the number of asymmetric dyads.
- `null`: if `method="probability"`, the probability of obtaining a null dyad; otherwise, the number of null dyads.
- `method`: the generation method to use. "probability" results in a multinomial dyad distribution (conditional on the underlying rates), while "exact" results in a uniform draw conditional on the exact dyad distribution.
- `return.as.edgelist`: logical; should the resulting graphs be returned in edgelist form?

**Details**

A simple generalization of the Erdos-Renyi family, the U|MAN distributions are uniform on the set of graphs, conditional on order (size) and the dyad census. As with the E-R case, there are two U|MAN variants. The first (corresponding to `method="probability"`) takes dyad states as independent multinomials with parameters `m` (for mutuals), `a` (for asymmetrics), and `n` (for nulls). The resulting pmf is then

\[
p(G = g|m, a, n) = \frac{(M + A + N)!}{M! A! N!} m^M a^A n^N,
\]

where `M`, `A`, and `N` are realized counts of mutual, asymmetric, and null dyads, respectively. (See `dyad.census` for an explication of dyad types.)

The second U|MAN variant is selected by `method="exact"`, and places equal mass on all graphs having the specified (exact) dyad census. The corresponding pmf is

\[
p(G = g|M, A, N) = \frac{M! A! N!}{(M + A + N)!}.
\]

U|MAN graphs provide a natural baseline model for networks which are constrained by size, density, and reciprocity. In this way, they provide a bridge between edgewise models (e.g., the E-R family) and models with higher order dependence (e.g., the Markov graphs).
Value

A matrix or array containing the drawn adjacency matrices

Note

The famous mathematicians referenced in this man page now have misspelled names, due to R’s difficulty with accent marks.

draw From the Watts-Strogatz Rewiring Model

rgws generates draws from the Watts-Strogatz rewired lattice model. Given a set of input graphs, rewire.ws performs a (dyadic) rewiring of those graphs.

Usage

rgws(n, nv, d, z, p, return.as.edgelist = FALSE)
rewire.ud(g, p, return.as.edgelist = FALSE)
rewire.ws(g, p, return.as.edgelist = FALSE)
rgws

Arguments

- n: the number of draws to take.
- nv: the number of vertices per lattice dimension.
- d: the dimensionality of the underlying lattice.
- z: the nearest-neighbor threshold for local ties.
- p: the dyadic rewiring probability.

return.as.edgelist

- logical: should the resulting graphs be returned in edgelist form?

Details

A Watts-Strogatz graph process generates a random graph via the following procedure. First, a d-dimensional uniform lattice is generated, here with nv vertices per dimension (i.e., $nv^d$ vertices total). Next, all z neighbors are connected, based on geodesics of the underlying lattice. Finally, each non-null dyad in the resulting augmented lattice is "rewired" with probability p, where the rewiring operation exchanges the initial dyad state with the state of a uniformly selected null dyad sharing exactly one endpoint with the original dyad. (In the standard case, this is equivalent to choosing an endpoint of the dyad at random, and then transferring the dyadic edges to/from that endpoint to another randomly chosen vertex. Hence the "rewiring" metaphor.) For $p=0$, the W-S process generates (deterministic) uniform lattices, approximating a uniform G(N,M) process as $p$ approaches 1. Thus, $p$ can be used to tune overall entropy of the process. A well-known property of the W-S process is that (for large $nv^d$ and small $p$) it generates draws with short expected mean geodesic distances (approaching those found in uniform graphs) while maintaining high levels of local "clustering" (i.e., transitivity). It has thus been proposed as one potential mechanism for obtaining "small world" structures.

rgws produces independent draws from the above process, returning them as an adjacency matrix (if $n=1$) or array (otherwise). rewire.ws, on the other hand, applies the rewiring phase of the W-S process to one or more input graphs. This can be used to explore local perturbations of the original graphs, conditioning on the dyad census. rewire.ud is similar to rewire.ws, save in that all dyads are eligible for rewiring (not just non-null dyads), and exchanges with non-null dyads are permitted. This process may be easier to work with than standard W-S rewiring in some cases.

Value

A graph or graph stack containing draws from the appropriate W-S process.

Warning

Remember that the total number of vertices in the graph is $nv^d$. This can get out of hand very quickly.

Note

rgws generates non-toroidal lattices; some published work in this area utilizes underlying toroids, so users should check for this prior to comparing simulations against published results.

rmperm

Randomly Permute the Rows and Columns of an Input Matrix

Description

Given an input matrix (or stack thereof), rmperm performs a (random) simultaneous row/column permutation of the input data.

Usage

rmperm(m)

Arguments

m a matrix, or stack thereof (or a graph set, for that matter).

Details

Random matrix permutations are the essence of the QAP test; see qaptest for details.

Value

The permuted matrix (or matrices)

Author(s)

Carter T. Butts (buttsc@uci.edu)
rperm

See Also

rperm

Examples

```r
#Generate an input matrix
g <- rgraph(5)
g #Examine it

#Examine a random permutation
rmperm(g)
```

rperm

Draw a Random Permutation Vector with Exchangeability Constraints

Description

Draws a random permutation on `1:length(exchange.list)` such that no two elements whose corresponding `exchange.list` values are different are interchanged.

Usage

```r
rperm(exchange.list)
```

Arguments

- `exchange.list`
  - A vector such that the permutation vector may exchange the ith and jth positions iff `exchange.list[i] == exchange.list[j]`

Details

`rperm` draws random permutation vectors given the constraints of exchangeability described above. Thus, `rperm(c(0, 0, 0, 0))` returns a random permutation of four elements in which all exchanges are allowed, while `rperm(c(1, 1, "a", "a"))` (or similar) returns a random permutation of four elements in which only the first/second and third/fourth elements may be exchanged. This turns out to be quite useful for searching permutation spaces with exchangeability constraints (e.g., for structural distance estimation).

Value

A random permutation vector satisfying the given constraints

Author(s)

Carter T. Butts (buttsc@uci.edu)

rperm(c("a",4,"x",2))  # Fix all elements (the identity permutation)

sdmat

Estimate the Structural Distance Matrix for a Graph Stack

Description

Estimates the structural distances among all elements of `dat` using the method specified in `method`.

Usage

```
somat(dat, normalize=FALSE, diag=FALSE, mode="digraph", output="matrix", method="mc", exchange.list=NULL, ...)
```

Arguments

dat  graph set to be analyzed.
normalize divide by the number of available dyads?
 diag  boolean indicating whether or not the diagonal should be treated as valid data. Set this true if and only if the data can contain loops. `diag` is `FALSE` by default.
 mode  string indicating the type of graph being evaluated. "digraph" indicates that edges should be interpreted as directed; "graph" indicates that edges are undirected. `mode` is set to "digraph" by default.
 output  "matrix" for matrix output, "dist" for a `dist` object.
 method  method to be used to search the space of accessible permutations; must be one of "none", "exhaustive", "anneal", "hillclimb", or "mc".
 exchange.list  information on which vertices are exchangeable (see below); this must be a single number, a vector of length `n`, or a `nx2` matrix.
 ...  additional arguments to `lab.optimize`.

Details

The structural distance between two graphs `G` and `H` is defined as

\[ d_S(G, H | L_G, L_H) = \min_{\ell_G, \ell_H} d(\ell(G), \ell(H)) \]

where `L_G` is the set of accessible permutations/labelings of `G`, and `\ell(G)` is a permutation/relabeling of the vertices of `G` (`\ell(G) \in L_G`). The set of accessible permutations on a given graph is determined by the *theoretical exchangeability* of its vertices; in a nutshell, two vertices are considered to be theoretically exchangeable for a given problem if all predictions under the conditioning theory are invariant to a relabeling of the vertices in question (see Butts and Carley (2001) for a more formal exposition). Where no vertices are exchangeable, the structural distance becomes the its labeled counterpart (here, the Hamming distance). Where all vertices are exchangeable, the structural
distance reflects the distance between unlabeled graphs; other cases correspond to distance under partial labeling.

The accessible permutation set is determined by the exchange.list argument, which is dealt with in the following manner. First, exchange.list is expanded to fill an nx2 matrix. If exchange.list is a single number, this is trivially accomplished by replication; if exchange.list is a vector of length n, the matrix is formed by cbinding two copies together. If exchange.list is already an nx2 matrix, it is left as-is. Once the nx2 exchangeability matrix has been formed, it is interpreted as follows: columns refer to graphs 1 and 2, respectively; rows refer to their corresponding vertices in the original adjacency matrices; and vertices are taken to be theoretically exchangeable iff their corresponding exchangeability matrix values are identical. To obtain an unlabeled distance (the default), then, one could simply let exchange.list equal any single number. To obtain the Hamming distance, one would use the vector 1:n.

Because the set of accessible permutations is, in general, very large (o(n!)), searching the set for the minimum distance is a non-trivial affair. Currently supported methods for estimating the structural distance are hill climbing, simulated annealing, blind monte carlo search, or exhaustive search (it is also possible to turn off searching entirely). Exhaustive search is not recommended for graphs larger than size 8 or so, and even this may take days; still, this is a valid alternative for small graphs. Blind monte carlo search and hill climbing tend to be suboptimal for this problem and are not, in general recommended, but they are available if desired. The preferred (and default) option for permutation search is simulated annealing, which seems to work well on this problem (though some tinkering with the annealing parameters may be needed in order to get optimal performance). See the help for lab.optimize for more information regarding these options.

Structural distance matrices may be used in the same manner as any other distance matrices (e.g., with multidimensional scaling, cluster analysis, etc.) Classical null hypothesis tests should not be employed with structural distances, and QAP tests are almost never appropriate (save in the uniquely labeled case). See cugtest for a more reasonable alternative.

Value

A matrix of distances (or an object of class dist)

Warning

The search process can be very slow, particularly for large graphs. In particular, the exhaustive method is order factorial, and will take approximately forever for unlabeled graphs of size greater than about 7-9.

Note

For most applications, sdmat is dominated by structdist; the former is retained largely for reasons of compatibility.

sedist

Find a Matrix of Distances Between Positions Based on Structural Equivalence

Description

sedist uses the graphs indicated by \( g \) in \( \text{dat} \) to assess the extent to which each vertex is structurally equivalent; \text{joint.analysis} determines whether this analysis is simultaneous, and \text{method} determines the measure of approximate equivalence which is used.

Usage

\[
\text{sedist}(\text{dat}, g=c(1:dim(\text{dat})[1]), \text{method}=\"\text{hamming}\", \text{joint.analysis}=\text{FALSE}, \text{mode}=\text{\"digraph\"}, \text{diag}=\text{FALSE}, \text{code.diss}=\text{FALSE})
\]

Arguments

- \text{dat}  
a graph or set thereof.
- \text{g}  
a vector indicating which elements of \( \text{dat} \) should be examined.
- \text{method}  
one of "correlation", "euclidean", "hamming", or "gamma".
- \text{joint.analysis}  
should equivalence be assessed across all networks jointly (TRUE), or individually within each (FALSE)?
- \text{mode}  
"digraph" for directed data, otherwise "graph".
- \text{diag}  
boolean indicating whether diagonal entries (loops) should be treated as meaningful data.
- \text{code.diss}  
reverse-code the raw comparison values.

Examples

\[
\begin{align*}
\text{#Generate two random graphs} \\
g &\leftarrow \text{array(dim=c(3,5,5))} \\
g[1,,] &\leftarrow \text{rgraph(5)} \\
g[2,,] &\leftarrow \text{rgraph(5)} \\
\text{#Copy one of the graphs and permute it} \\
g[3,,] &\leftarrow \text{rmperm(g[2,,])} \\
\text{#What are the structural distances between the labeled graphs?} \\
\text{sdmat(g, exchange.list=1:5)} \\
\text{#What are the structural distances between the underlying unlabeled graphs?} \\
\text{sdmat(g, method=\"anneal\", prob.init=0.9, prob.decay=0.85, freeze.time=50, full.neighborhood=TRUE)}
\end{align*}
\]
**Details**

`sedist` provides a basic tool for assessing the (approximate) structural equivalence of actors. (Two vertices i and j are said to be structurally equivalent if i->k iff j->k for all k.) SE similarity/difference scores are computed by comparing vertex rows and columns using the measure indicated by `method`:

1. correlation: the product-moment correlation
2. euclidean: the euclidean distance
3. hamming: the Hamming distance
4. gamma: the gamma correlation

Once these similarities/differences are calculated, the results can be used with a clustering routine (such as `equiv.clust`) or an MDS (such as `cmdscale`).

**Value**

A matrix of similarity/difference scores

**Note**

Be careful to verify that you have computed what you meant to compute, with respect to similarities/differences. Also, note that (despite its popularity) the product-moment correlation can give rather strange results in some cases.

```
sna is a package containing a range of tools for social network analysis. Supported functionality includes node and graph-level indices, structural distance and covariance methods, structural equivalence detection, $p^*$ modeling, random graph generation, and 2D/3D network visualization (among other things).

Details

Network data for sna routines can (except as noted otherwise) appear in any of the following forms:

- adjacency matrices (dimension $N \times N$);
- arrays of adjacency matrices, aka "graph stacks" (dimension $m \times N \times N$);
- sna edge lists (see below);
- sparse matrix objects (from the SparseM package);
- network objects (from the network package); or
- lists of adjacency matrices/arrays, sparse matrices, and/or network objects.

Within the package documentation, the term "graph" is used generically to refer to any or all of the above (with multiple graphs being referred to as a graph stack). Note that usage of sparse matrix or network objects requires that the SparseM or network package be installed, respectively. (No additional packages are required for use of adjacency matrices/arrays or lists thereof.) In general, sna routines attempt to make intelligent decisions regarding the processing of multiple graphs, but common sense is always advised; certain functions, in particular, have more specific data requirements. Calling sna functions with inappropriate input data can produce interesting results.

One special data type supported by the sna package (as of version 2.0) is the sna edgelist. This is a simple data format that is well-suited to representing large, sparse graphs. (As of version 2.0, many package routines also process data in this form natively, so using it can produce significant savings of time and/or memory. Prior to 2.0, all package functions coerced input data to adjacency matrix form.) An sna edgelist is a three-column matrix, containing (respectively) senders, receivers, and values for each edge in the graph. (Unvalued edges should have a value of 1.) Note that this form is invariant to the number of edges in the graph: if there are no edges, then the edgelist is a degenerate matrix of dimension 0 by 3. Edgelists for undirected graphs should be coded as fully mutual digraphs (as would be the case with an adjacency matrix), with two edges per dyad (one $(i,j)$ edge, and one $(j,i)$ edge). Graph size for an sna edgelist matrix is indicated by a mandatory numeric attribute, named "n". Vertex names may be optionally specified by a vector-valued attribute named "vnames". In the case of two-mode data (i.e., data with an enforced bipartition), it is possible to indicate this status via the optional "bipartite" attribute. Vertices in a two-mode edgelist should be grouped in mode order, with "n" equal to the total number of vertices (across both modes) and "bipartite" equal to the number of vertices in the first mode.

Direct creation of sna edgelists can be performed by creating a three-column matrix and using the attr function to create the required "n" attribute. Alternately, the internal function as.edgelist.sna can be used to coerce data in any of the above forms to an sna edgelist. By turns, the internal function as.sociomatrix.sna can be used to convert any of these data types to adjacency matrix form.
To get started with sna, try obtaining viewing the list of available functions. This can be accomplished via the command `library(help=sna).

**Note**

If you use this package and/or software manual in your work, a citation would be appreciated. References to the current versions are:

See also the following paper, which explores the package in some detail:

If utilizing a contributed routine, please also consider recognizing the author(s) of that specific function. Contributing authors, if any, are listed on the relevant manual pages. Your support helps to encourage the growth of the sna package, and is greatly valued!

Deprecated
**Graphical Operators**

**Description**

These operators allow for algebraic manipulation of graph adjacency matrices.

**Usage**

\[ x \mathbin{\%c\%} y \]

**Arguments**

- **x**: an (unvalued) adjacency matrix.
- **y**: another (unvalued) adjacency matrix.

**Details**

Currently, only one operator is supported. \( x \mathbin{\%c\%} y \) returns the adjacency matrix of the composition of graphs with adjacency matrices \( x \) and \( y \) (respectively). (Note that this may contain loops.)

**Value**

The resulting adjacency matrix.

**Author(s)**

Carter T. Butts (buttsc@uci.edu)

**References**

**Examples**

```r
# Create an in-star
g <- matrix(0, 6, 6)
g[2:6, 1] <- 1
gplot(g)

# Compose g with its transpose
gcgt <- g%tc%(g)
gplot(gcgt, diag = TRUE)
gcgt
```
sr2css  Convert a Row-wise Self-Report Matrix to a CSS Matrix with Missing Observations

Description

Given a matrix in which the ith row corresponds to i’s reported relations, sr2css creates a graph stack in which each element represents a CSS slice with missing observations.

Usage

sr2css(net)

Arguments

net an adjacency matrix.

Details

A cognitive social structure (CSS) is an nxnxn array in which the ith matrix corresponds to the ith actor’s perception of the entire network. Here, we take a conventional self-report data structure and put it in CSS format for routines (such as bbnam) which require this.

Value

An array (graph stack) containing the CSS

Note

A row-wise self-report matrix doesn’t contain a great deal of data, and the data in question is certainly not an ignorable sample of the individual’s CSS for most purposes. The provision of this routine should not be perceived as license to substitute SR for CSS data at will.

**Examples**

```r
stackcount(rgraph(4,8))==8
```

---

**stresscent**

*Compute the Stress Centrality Scores of Network Positions*

**Description**

`stresscent` takes one or more graphs (`dat`) and returns the stress centralities of positions (selected by `nodes`) within the graphs indicated by `g`. Depending on the specified mode, stress on directed or undirected geodesics will be returned; this function is compatible with `centralization`, and will return the theoretical maximum absolute deviation (from maximum) conditional on size (which is used by `centralization` to normalize the observed centralization score).

**Usage**

```r
stresscent(dat, g=1, nodes=NULL, gmode="digraph", diag=FALSE, tmaxdev=FALSE, cmode="directed", geodist.precomp=NULL, rescale=FALSE, ignore.eval=TRUE)
```
Arguments

dat  one or more input graphs.
g    Integer indicating the index of the graph for which centralities are to be calculated (or a vector thereof). By default, \( g = 1 \).

nodes list indicating which nodes are to be included in the calculation. By default, all nodes are included.
gmode string indicating the type of graph being evaluated. "digraph" indicates that edges should be interpreted as directed; "graph" indicates that edges are undirected. \( gmode \) is set to "digraph" by default.
diag boolean indicating whether or not the diagonal should be treated as valid data. Set this true if and only if the data can contain loops. \( diag \) is FALSE by default.
tmaxdev boolean indicating whether or not the theoretical maximum absolute deviation from the maximum nodal centrality should be returned. By default, \( tmaxdev = \text{FALSE} \).
cmode string indicating the type of betweenness centrality being computed (directed or undirected geodesics).

geodist.precomp a \texttt{geodist} object precomputed for the graph to be analyzed (optional).

rescale if true, centrality scores are rescaled such that they sum to 1.

ignore.eval logical; should edge values be ignored when calculating density?

Details

The stress of a vertex, \( v \), is given by

\[
C_S(v) = \sum_{i,j: i \neq j, i \neq v, j \neq v} g_{ijk}
\]

where \( g_{ijk} \) is the number of geodesics from \( i \) to \( k \) through \( j \). Conceptually, high-stress vertices lie on a large number of shortest paths between other vertices; they can thus be thought of as “bridges” or “boundary spanners.” Compare this with \texttt{betweenness}, which weights shortest paths by the inverse of their redundancy.

Value

A vector, matrix, or list containing the centrality scores (depending on the number and size of the input graphs).

Note

Judicious use of \texttt{geodist.precomp} can save a great deal of time when computing multiple path-based indices on the same network.

structdist  
Find the Structural Distances Between Two or More Graphs

Description

structdist returns the structural distance between the labeled graphs g1 and g2 in stack dat based on Hamming distance for dichotomous data, or else the absolute (manhattan) distance. If normalize is true, this distance is divided by its dichotomous theoretical maximum (conditional on IV(G)).

Usage

structdist(dat, g1=NULL, g2=NULL, normalize=FALSE, diag=FALSE,  
mode="digraph", method="anneal", reps=1000, prob.init=0.9, 
prob.decay=0.85, freeze.time=25, full.neighborhood=TRUE, 
mut=0.05, pop=20, trials=5, exchange.list=NULL)

Arguments

dat one or more input graphs.
g1 a vector indicating which graphs to compare (by default, all elements of dat).
g2 a vector indicating against which the graphs of g1 should be compared (by default, all graphs).
normalize divide by the number of available dyads?
diag boolean indicating whether or not the diagonal should be treated as valid data. Set this true if and only if the data can contain loops. diag is FALSE by default.
mode string indicating the type of graph being evaluated. "digraph" indicates that edges should be interpreted as directed; "graph" indicates that edges are undirected. mode is set to "digraph" by default.
method method to be used to search the space of accessible permutations; must be one of "none", "exhaustive", "anneal", "hillclimb", or "mc".
reps number of iterations for Monte Carlo method.
prob.init initial acceptance probability for the annealing routine.
prob.decay cooling multiplier for the annealing routine.
freeze.time freeze time for the annealing routine.
full.neighborhood should the annealer evaluate the full neighborhood of pair exchanges at each iteration?
mut GA Mutation rate (currently ignored).
The structural distance between two graphs $G$ and $H$ is defined as

$$d_S(G, H | L_G, L_H) = \min_{L_G, L_H} d(\ell(G), \ell(H))$$

where $L_G$ is the set of accessible permutations/labelings of $G$, and $\ell(G)$ is a permutation/relabeling of the vertices of $G$ ($\ell(G) \in L_G$). The set of accessible permutations on a given graph is determined by the theoretical exchangeability of its vertices; in a nutshell, two vertices are considered to be theoretically exchangeable for a given problem if all predictions under the conditioning theory are invariant to a relabeling of the vertices in question (see Butts and Carley (2001) for a more formal exposition). Where no vertices are exchangeable, the structural distance becomes the its labeled counterpart (here, the Hamming distance). Where all vertices are exchangeable, the structural distance reflects the distance between unlabeled graphs; other cases correspond to distance under partial labeling.

The accessible permutation set is determined by the `exchange.list` argument, which is dealt with in the following manner. First, `exchange.list` is expanded to fill an $nx2$ matrix. If `exchange.list` is a single number, this is trivially accomplished by replication; if `exchange.list` is a vector of length $n$, the matrix is formed by `cbind`ing two copies together. If `exchange.list` is already an $nx2$ matrix, it is left as-is. Once the $nx2$ exchangeability matrix has been formed, it is interpreted as follows: columns refer to graphs 1 and 2, respectively; rows refer to their corresponding vertices in the original adjacency matrices; and vertices are taken to be theoretically exchangeable iff their corresponding exchangeability matrix values are identical. To obtain an unlabeled distance (the default), then, one could simply let `exchange.list` equal any single number. To obtain the Hamming distance, one would use the vector $1:n$.

Because the set of accessible permutations is, in general, very large ($o(n!)$), searching the set for the minimum distance is a non-trivial affair. Currently supported methods for estimating the structural distance are hill climbing, simulated annealing, blind monte carlo search, or exhaustive search (it is also possible to turn off searching entirely). Exhaustive search is not recommended for graphs larger than size 8 or so, and even this may take days; still, this is a valid alternative for small graphs. Blind monte carlo search and hill climbing tend to be suboptimal for this problem and are not, in general recommended, but they are available if desired. The preferred (and default) option for permutation search is simulated annealing, which seems to work well on this problem (though some tinkering with the annealing parameters may be needed in order to get optimal performance). See the help for `lab.optimize` for more information regarding these options.

Structural distance matrices may be used in the same manner as any other distance matrices (e.g., with multidimensional scaling, cluster analysis, etc.) Classical null hypothesis tests should not be employed with structural distances, and QAP tests are almost never appropriate (save in the uniquely labeled case). See `cugtest` for a more reasonable alternative.

**Value**

A structural distance matrix
Warning

The search process can be very slow, particularly for large graphs. In particular, the exhaustive method is order factorial, and will take approximately forever for unlabeled graphs of size greater than about 7-9.

Note

Consult Butts and Carley (2001) for advice and examples on theoretical exchangeability.

# Copy one of the graphs and permute it
gh <- rmperm(g[2, ,])

# What are the structural distances between the labeled graphs?
structdist(g, exchange.list = 1:5)

# What are the structural distances between the underlying unlabeled graphs?
structdist(g, method = "anneal", prob.init = 0.9, prob.decay = 0.85, freeze.time = 50, full.neighborhood = TRUE)
**structure.statistics**

**Arguments**
- `dat`: one or more input graphs.
- `geodist.precomp`: a `geodist` object (optional).

**Details**
Let $G = (V, E)$ be a graph of order $N$, and let $d(i, j)$ be the geodesic distance from vertex $i$ to vertex $j$ in $G$. The "structure statistics" of $G$ are then given by the series $s_0, \ldots, s_{N-1}$, where

$$s_i = \frac{1}{N^2} \sum_{j \in V} \sum_{k \in V} I(d(j, k) \leq i)$$

and $I$ is the standard indicator function. Intuitively, $s_i$ is the expected fraction of $G$ which lies within distance $i$ of a randomly chosen vertex. As such, the structure statistics provide an index of global connectivity.

Structure statistics have been of particular importance to biased net theorists, because of the link with Rapoport’s original tracing model. They may also be used along with component distributions or connectedness scores as descriptive indices of connectivity at the graph-level.

**Value**
A vector, matrix, or list (depending on `dat`) containing the structure statistics.

**Note**
The term "structure statistics" has been used somewhat loosely in the literature, a trend which seems to be accelerating. Users should carefully check references before comparing results generated by this routine with those appearing in published work.

symmetrize

Symmetrize an Adjacency Matrix

Description

Symmetrizes the elements of mats according to the rule in rule.

Usage

symmetrize(mats, rule="weak", return.as.edgelist=FALSE)

Arguments

mats a graph or graph stack.
rule one of “upper”, “lower”, “strong” or “weak”.
return.as.edgelist logical; should the symmetrized graphs be returned in edgelist form?

Details

The rules used by symmetrize are as follows:

1. upper: Copy the upper triangle over the lower triangle
2. lower: Copy the lower triangle over the upper triangle
3. strong: i<->j iff i->j and i<-j (AND rule)
4. weak: i<->j iff i->j or i<-j (OR rule)

Value

The symmetrized graph stack

*Compute the Davis and Leinhardt Triad Census*

Description

`triad.census` returns the Davis and Leinhardt triad census of the elements of `dat` indicated by `g`.

Usage

```r
triad.census(dat, g=NULL, mode = c("digraph", "graph"))
```

Arguments

- `dat`: a graph or graph stack.
- `g`: the elements of `dat` to process.
- `mode`: string indicating the directedness of edges; "digraph" implies a directed structure, whereas "graph" implies an undirected structure.

Details

The Davis and Leinhardt triad census consists of a classification of all directed triads into one of 16 different categories; the resulting distribution can be compared against various null models to test for the presence of configurational biases (e.g., transitivity bias). `triad.census` is a front end for the `triad.classify` routine, performing the classification for all triads within the selected graphs. The results are placed in the order indicated by the column names; this is the same order as presented in the `triad.classify` documentation, to which the reader is referred for additional details.

In the undirected case, the triad census reduces to four states (based on the number of edges in each triad). Where `mode == "graph"`, this is returned instead.

Compare `triad.census` to `dyad.census`, the dyadic equivalent.

Value

A matrix whose 16 columns contain the counts of triads by class for each graph, in the directed case. In the undirected case, only 4 columns are used.
**Warning**

Valued data may cause strange behavior with this routine. Dichotomize the data first.

**Author(s)**

Carter T. Butts (buttsc@uci.edu)

**References**

**See Also**

`triad.classify`, `dyad.census`, `kcycle.census`, `kpath.census`, `gtrans`

**Examples**

```r
# Generate a triad census of random data with varying densities
triad.census(rgraph(15,5,tprob=c(0.1,0.25,0.5,0.75,0.9)))
```

---

**Description**

`triad.classify` returns the Davis and Leinhardt classification of the triad indicated by `tri` in the `g`th graph of stack `dat`.

**Usage**

```r
triad.classify(dat, g=1, tri=c(1, 2, 3), mode=c("digraph", "graph"))
```

**Arguments**

- `dat` : a graph or graph stack.
- `g` : the index of the graph to be analyzed.
- `tri` : a triple containing the indices of the triad to be classified.
- `mode` : string indicating the directedness of edges; "digraph" implies a directed structure, whereas "graph" implies an undirected structure.
Every unoriented directed triad may occupy one of 16 distinct states. These states were used by Davis and Leinhardt as a basis for classifying triads within a larger structure; the distribution of triads within a graph (see `triad.census`), for instance, is linked to a range of substantive hypotheses (e.g., concerning structural balance). The Davis and Leinhardt classification scheme describes each triad by a string of four elements: the number of mutual (complete) dyads within the triad; the number of asymmetric dyads within the triad; the number of null (empty) dyads within the triad; and a configuration code for the triads which are not uniquely distinguished by the first three distinctions. The complete list of classes is as follows.

\[
\begin{align*}
003 & \quad a \not\leftrightarrow b \not\leftrightarrow c, a \not\leftrightarrow c \\
012 & \quad a 
\rightarrow b \not\leftrightarrow c, a \not\leftrightarrow c \\
102 & \quad a \leftrightarrow b \not\leftrightarrow c, a \not\leftrightarrow c \\
021D & \quad a \leftrightarrow b \leftrightarrow c, a \not\leftrightarrow c \\
021U & \quad a \rightarrow b \leftrightarrow c, a \not\leftrightarrow c \\
021C & \quad a \rightarrow b \rightarrow c, a \not\leftrightarrow c \\
111D & \quad a \not\leftrightarrow b \rightarrow c, a \leftrightarrow c \\
111U & \quad a \not\leftrightarrow b \leftrightarrow c, a \leftrightarrow c \\
030T & \quad a \rightarrow b \leftrightarrow c, a \rightarrow c \\
030C & \quad a \leftrightarrow b \leftrightarrow c, a \rightarrow c \\
201 & \quad a \leftrightarrow b \not\leftrightarrow c, a \leftrightarrow c \\
120D & \quad a \leftrightarrow b \leftrightarrow c, a \leftrightarrow c \\
120U & \quad a \rightarrow b \leftrightarrow c, a \leftrightarrow c \\
120C & \quad a \rightarrow b \rightarrow c, a \leftrightarrow c \\
210 & \quad a \rightarrow b \leftrightarrow c, a \leftrightarrow c \\
300 & \quad a \leftrightarrow b \leftrightarrow c, a \leftrightarrow c
\end{align*}
\]

These codes are returned by `triad.classify` as strings. In the undirected case, only four triad states are possible (corresponding to the number of edges in the triad). These are evaluated for `mode="graph"`, with the return value being the number of edges.

**Value**

A string containing the triad classification, or `NA` if one or more edges were missing

**Warning**

Valued data and/or loops may cause strange behavior with this routine. Dichotomize/remove loops first.

triad.census, gtrans

Examples

# Generate a random graph
g<-rgraph(10)

# Classify the triads (1,2,3) and (2,3,4)
triad.classify(g,tri=c(1,2,3))
triad.classify(g,tri=c(1,2,3))

# Plot the triads in question
gplot(g[1:3,1:3])
gplot(g[2:4,2:4])

upper.tri.remove  Remove the Upper Triangles of Adjacency Matrices in a Graph Stack

Description

Returns the input graph stack, with the upper triangle entries removed/replaced as indicated.

Usage

upper.tri.remove(dat, remove.val=NA)

Arguments

dat a graph or graph stack.
remove.val the value with which to replace the existing upper triangles.

Details

upper.tri.remove is simply a convenient way to apply g[upper.tri(g)]<-remove.val to an entire stack of adjacency matrices at once.

Value

The updated graph stack.

Author(s)

Carter T. Butts (buttsc@uci.edu)

See Also

upper.tri, lower.tri.remove, diag.remove
Examples

```r
# Generate a random graph stack
g <- rgraph(3, 5)
# Remove the upper triangles
g <- upper.tri.remove(g)
```

**write.dl**  
*Write Output Graphs in DL Format*

**Description**
Writes a graph stack to an output file in DL format.

**Usage**
```r
write.dl(x, file, vertex.lab = NULL, matrix.lab = NULL)
```

**Arguments**
- `x`: a graph or graph stack, of common order.
- `file`: a string containing the filename to which the data should be written.
- `vertex.lab`: an optional vector of vertex labels.
- `matrix.lab`: an optional vector of matrix labels.

**Details**
DL format is used by a number of software packages (including UCINET and Pajek) to store network data. `write.dl` saves one or more (possibly valued) graphs in DL edgelist format, along with vertex and graph labels (if desired). These files can, in turn, be used to import data into other software packages.

**Value**
None.

**Author(s)**
Carter T. Butts <butsc@uci.edu>

**See Also**
- `write.nos`

**Examples**
```r
## Not run:
# Generate a random graph stack
g <- rgraph(5, 10)
# This would save the graphs in DL format
write.dl(g, file = "testfile.dl")
## End(Not run)
```
Description

Writes a graph stack to an output file in NOS format.

Usage

\texttt{write.nos(x, file, row.col = NULL, col.col = NULL)}

Arguments

- \texttt{x}: a graph or graph stack (all graphs must be of common order).
- \texttt{file}: string containing the output file name.
- \texttt{row.col}: vector of row labels (or "row colors").
- \texttt{col.col}: vector of column labels ("column colors").

Details

NOS format consists of three header lines, followed by a whitespace delimited stack of raw adjacency matrices; the format is not particularly elegant, but turns up in certain legacy applications (mostly at CMU). \texttt{write.nos} provides a quick and dirty way of writing files NOS, which can later be retrieved using \texttt{read.nos}.

The content of the NOS format is as follows:

\[
\begin{align*}
<m> &<n> <o> \\
<kr1> <kr2> ... <krn> <kc1> <kc2> ... <kcn> \\
<a111> <a112> ... <a11o> \\
<a121> <a122> ... <a12o> \\
... \\
<a1n1> <a1n2> ... <a1no> \\
<a211> <a212> ... <a21o> \\
... \\
<a2n1> <a2n2> ... <a2no> \\
... \\
<amn1> <amn2> ... <amno>
\end{align*}
\]

where \texttt{<abcd>} is understood to be the value of the \texttt{c->d} edge in the \texttt{b}th graph of the file. (As one might expect, \texttt{m}, \texttt{n}, and \texttt{o} are the numbers of graphs (matrices), rows, and columns for the data, respectively.) The "k" line contains a list of row and column "colors", categorical variables associated with each row and column, respectively. Although originally intended to communicate exchangability information, these can be used for other purposes (though there are easier ways to deal with attribute data these days).

Note that NOS format only supports graph stacks of common order; graphs of different sizes cannot be stored within the same file.
Value

None.
